Surgical History and Physical Examination

Surgical Documentation

S. E. Wilson, MD

Surgical History and Physical Examination

Identifying Data: Patient's name, age, race, sex; referring physician.
Chief Compliant: Reason given by patient for seeking surgical care and the duration of the symptom.
History of Present Illness (HPI): Describe the course of the patient's illness, including when it began, character of the symptoms; pain onset (gradual or rapid), precise character of pain (constant, intermittent, cramping, stabbing, radiating); other factors associated with pain (defecation, urination, eating, strenuous activities); location where the symptoms began; aggravating or relieving factors. Vomiting (color, character, blood, coffee-ground emesis, frequency, associated pain). Change in bowel habits; rectal bleeding, character of blood (clots, bright or dark red), trauma; recent weight loss or anorexia; other related diseases; past diagnostic testing.
Past Medical History (PMH): Previous operations and indications; dates and types of procedures; serious injuries, hospitalizations; diabetes, hypertension, peptic ulcer disease, asthma, heart disease; hernia, gallstones.
Medications: Aspirin, anticoagulants, hypertensive and cardiac medications, diuretics.
Allergies: Penicillin, codeine, iodine.
Family History: Medical problems in relatives. Family history of colon cancer, cardiovascular disease.
Social History: Alcohol, smoking, drug usage, occupation, daily activity.
Review of Systems (ROS):
  General: Weight gain or loss; loss of appetite, fever, fatigue, night sweats.
  Activity level.
  HEENT: Headaches, seizures, sore throat, masses, dentures.
  Respiratory: Cough, sputum, hemoptysis, dyspnea on exertion, ability to walk up flight of stairs.
  Cardiovascular: Chest pain, orthopnea, claudication, extremity edema.
  Gastrointestinal: Dysphagia, vomiting, abdominal pain, hematemesis, melena (black tarry stools), hematochezia (bright red blood per rectum), constipation, change in bowel habits; hernia, hemorrhoids, gallstones.
  Genitourinary: Dysuria, hesitancy, hematuria, discharge; impotence, prostate problems, urinary frequency.
  Gynecological: Last menstrual period, gravida, para, abortions, length of regular cycle and periods, birth control.
  Skin: Easy bruising, bleeding tendencies.
  Neurological: Stroke, transient ischemic attacks, weakness.

Surgical Physical Examination

General appearance: Note whether the patient looks "ill," well, or malnourished.
Vital Signs: Temperature, respirations, heart rate, blood pressure, weight.
Eyes: Pupils equally round and react to light (PERRL); extraocular movements intact (EOMI).
Neck: Jugular venous distention (JVD), thyromegaly, masses, bruits; lymphadenopathy; trachea midline.
6 Preoperative Preparation of the Surgical Patient

Chest: Equal expansion, dullness to percussion; rales, rhonchi, breath sounds.

Heart: Regular rate and rhythm (RRR), first and second heart sounds; murmurs (grade 1-6), pulses (graded 0-2+).

Breast: Skin retractions, erythema, tenderness, masses (mobile, fixed), nipple discharge, axillary or supraclavicular node enlargement.

Abdomen: Contour (flat, scaphoid, obese, distended), scars, bowel sounds, bruits, tenderness, masses, liver span; splenomegaly, guarding, rebound, percussion note (dull, tympanic), pulsatile masses, costovertebral angle tenderness (CVAT), abdominal hernias.

Genitourinary: Inguinal hernias, testicles, varicoceles; urethral discharge, varicocele.

Extremities: Skin condition, edema (grade 1-4+); cyanosis, clubbing, pulses (radial, ulnar, femoral, popliteal, posterior tibial, dorsalis pedis; simultaneous palpation of radial and femoral pulses). Grading of pulses: 0 = absent; 1+ weak; 2+ normal; 3+ very strong (arterial dilation).

Rectal Exam: Masses, tenderness, hemorrhoids, prostate masses; bimanual palpation, guaiac test for occult blood.

Neurological: Mental status, cranial nerves, gait, strength (graded 0-5); tendon reflexes, sensory testing.

Laboratory Evaluation: Electrolytes (sodium, potassium, bicarbonate, chloride, BUN, creatinine), glucose, liver function tests, INR/PTT, CBC with differential; X-rays, ECG (if older than 35 yrs or cardiovascular disease), urine analysis.

Assessment (Impression): Assign a number to each problem and discuss each problem. Begin with most important problem and rank in order.

Plan: Discuss surgical plans for each numbered problem, including preoperative testing, laboratory studies, medications, antibiotics, endoscopy.

Preoperative Preparation of the Surgical Patient

1. Review the patient’s history and physical examination, and write a preoperative note assessing the patient’s overall condition and operative risk.

2. Preoperative laboratory evaluation: Electrolytes, BUN, creatinine, INR/PTT, CBC, platelet count, UA, ABG, pulmonary function test. Chest x-ray (>35 yrs old), EKG (if older than 35 yrs old or if cardiovascular disease). Type and cross for an appropriate number of units of blood. No screening laboratory tests are required in the healthy patient.

3. Skin preparation: Patient to shower and scrub the operative site with germicidal soap (Hibiclens) on the night before surgery. On the day of surgery, hair should be removed with an electric clipper or shaved just prior to operation.

4. Prophylactic antibiotics or endocarditis prophylaxis if indicated.

5. Preoperative incentive spirometry on the evening prior to surgery may be indicated for patients with pulmonary disease.

6. Thromboembolic prophylaxis should be provided for selected, high-risk patients.

8. IV and monitoring lines: At least one 18-gauge IV for initiation of anesthesia. Arterial catheter and pulmonary artery catheters (Swan-Ganz) if indicated. Patient to void on call prior to going to the operating room.

9. Medications. Preoperative sedation as ordered by anesthesiologist. Maintenance medications to be given the morning of surgery with a sip of water. Diabetics should receive one half of their usual AM insulin dose, and
Admitting and Preoperative Orders

10. **Bowel preparation**
Bowel preparation is required for upper or lower GI tract procedures.

**Mechanical Prep:** Day 1: Clear liquid diet, laxative (milk of magnesium 30 cc or magnesium citrate 250 cc), tap water or Fleet enemas until clear. Day 2: Clear liquid diet, NPO, laxative. Day 3: Operation.

**Whole Gut Lavage:** Polyethylene glycol electrolyte solution (GoLytely).
Day 1: 2 liters PO or per nasogastric tube over 5 hours. Clear liquid diet.
Day 2: Operation.

**Oral Antibiotic Prep:** One day prior to surgery, after mechanical or whole gut lavage, give neomycin 1 gm and erythromycin 250 mg at 1 p.m., 2 p.m., 11 p.m.

11. **Preoperative IV antibiotics:** Initiate preoperatively and give one dose during operation and one dose of antibiotic postoperatively. Cefotetan (Cefotan), 1 gm IV q12h, for bowel flora, or cefazolin (Ancef), 1 gm IVPB q8h x 3 doses, for clean procedures.

12. **Anticoagulants:** Discontinue Coumadin 5 days preop and check PT; stop IV heparin 6 hours prior to surgery.

Admitting and Preoperative Orders

**Admit to:** Ward, ICU, or preoperative room.
**Diagnosis:** Intended operation and indication.
**Condition:** Stable
**Vital Signs:** Frequency of vital signs; input and output recording; neurological or vascular checks. Notify physician if blood pressure <90/60, >160/110; pulse >110; pulse <60; temperature >101.5; urine output <35 cc/h for >2 hours; respiratory rate >30.
**Activity:** Bed rest or ambulation; bathroom privileges.
**Allergies:** No known allergies
**Diet:** NPO
**IV Orders:** D5 ½ NS at 100 cc/hour.
**Oxygen:** 6 L/min by nasal canula.
**Drains:** Foley catheter to closed drainage. Nasogastric tube at low intermittent suction. Other drains, tubes, dressing changes. Orders for irrigation of tubes.
**Medications:** Antibiotics to be initiated immediately preoperatively; additional dose during operation and 1 dose of antibiotic postoperatively. Cefotetan (Cefotan), 1 gm IV q12h, for bowel flora, or cefazolin (Ancef) 1 gm IVPB q8h x 3 doses; for clean procedures.
**Labs and Special X-Rays:** Electrolytes, BUN, creatinine, INR/PTT, CBC, platelet count, UA, ABG, pulmonary function tests. Chest x-ray (if >35 yrs old), EKG (if older then 35 yrs old or if cardiovascular disease). Type and cross for an appropriate number of units of blood.
8 Preoperative Note

Preoperative Note

Preoperative Diagnosis:
Procedure Planned:
Type of Anesthesia Planned:
Laboratory Data: Electrolytes, BUN, creatinine, CBC, INR/PTT, UA, EKG, chest x-ray; type and screen for blood or cross match if indicated; liver function tests, ABG.
Risk Factors: Cardiovascular, pulmonary, hepatic, renal, coagulopathic, nutritional risk factors.
American Surgical Association (ASA) grading of surgical risk: 1=normal; 2= mild systemic disease; 3= severe systemic disease; 4= disease with major threat to life; 5= not expected to survive.
Consent: Document explanation to patient of risks and benefits of the procedure and alternative treatments. Document patient’s or guardian’s informed consent and understanding of the procedure. Obtain signed consent form.
Allergies:
Major Medical Problems:
Medications:
Special Requirements: Signed blood transfusion consent form; documentation that breast procedure patients have been given an information brochure.

Brief Operative Note

This note should be written in chart immediately after the surgical procedure.
Date of the Procedure:
Preoperative Diagnosis:
Postoperative Diagnosis:
Procedure:
Operative Findings:
Names of Surgeon and Assistants:
Anesthesia: General endotracheal, spinal, epidural, regional or local.
Estimated Blood Loss (EBL):
Fluids and Blood Products Administered During Procedure:
Urine output:
Specimens: Pathology specimens, cultures, blood samples.
Intraoperative X-rays:
Drains:
Condition of Patient: Stable

Operative Report

This full report should be dictated at the conclusion of the surgical procedure.
Identifying Data: Name of patient, medical record number; name of dictating physician, date of dictation.
Attending Surgeon and Service:
Date of Procedure:
Preoperative Diagnosis:
Postoperative Diagnosis:
Postoperative Check

**Procedure Performed:**

**Names of Surgeon and Assistants:**

**Type of Anesthesia Used:**

**Estimated Blood Loss (EBL):**

**Fluid and Blood Products Administered During Operation:**

**Specimens:** Pathology, cultures, blood samples.

**Drains and Tubes Placed:**

**Complications:**

**Consultations Intraoperatively:**

**Indications for Surgery:** Brief history of patient and indications for surgery.

**Findings:** Describe gross findings and frozen section results relayed to operating room.

**Description of Operation:** Position of patient; skin prep and draping; location and types of incisions; details of procedure from beginning to end, including description of surgical findings, both normal and abnormal. Intraoperative studies or x-rays, hemostatic and closure techniques; dressings applied. Needle and sponge counts as reported by operative nurse. Patient’s condition and disposition. Send copies of report to surgeons and referring physicians.

---

**Postoperative Check**

A postoperative check should be completed on the evening after surgery. This check is similar to a daily progress note.

<table>
<thead>
<tr>

10 Postoperative Orders

Postoperative Orders

1. **Transfer:** From recovery room to surgical ward when stable.
2. **Vital Signs:** q4h, f&O q4h x 24h.
3. **Activity:** Bed rest; ambulate in 6-8 hours if appropriate. Incentivespirometer q1h while awake.
4. **Diet:** NPO x 8h, then sips of water. Advance to clear liquids to regular diet as tolerated.
5. **IV Fluids:** IV D5 LR or D5½ NS at 125 cc/h (KCL, 20 mEq/L if indicated), Foley to gravity.
6. **Medications:**
   - Cefazolin (Ancef) 1 gm IVPB q8h x 3 doses; if indicated for prophylaxis in clean cases
   - Cefotetan (Cefotan) 1 gm IV q12h x 2 doses for clean contaminated cases.
   - Meperidine (Demerol) 50 mg IV/IM q3-4h prn pain
   - Hydroxyzine (Vistaril) 25-50 mg IV/IM q3-4h prn nausea
   - Prochlorperazine (Compazine) 10 mg IV/IM q4-6h prn nausea or suppository q4h prn.
7. **Laboratory Evaluation:** CBC, SMA7, chest x-ray in AM if indicated.

Postoperative Surgical Management

I. **Postoperative day number 1**
   - A. Assess the patient’s level of pain, lungs, cardiac status, flatulence, and bowel movement. Examine for distension, tenderness, bowel sounds; wound drainage, bleeding from incision.
   - B. Discontinue IV infusion when taking adequate PO fluids. Discontinue Foley catheter, and use in-and-out catheterization for urinary retention.
   - C. Ambulate as tolerated; incentivespirometer, hematocrit and hemoglobin.
   - D. Acetaminophen/codeine (Tylenol #3) 1-2 PO q4-6h prn pain.
   - E. Colace 100 mg PO bid.
   - F. Consider prophylaxis for deep vein thrombosis.

II. **Postoperative day number 2**
   - A. If passing gas or if bowel movement, advance to regular diet unless bowel resection.
   - B. Laxatives: Dulcolax suppository prn or Fleet enema prn or milk of magnesia; 30 cc PO prn constipation.

III. **Postoperative day number 3-7**
   - A. Check pathology report.
   - B. Remove staples and place steri-strips.
   - C. Consider discharge home on appropriate medications; follow up in 1-2 weeks for removal of sutures.
   - D. Write discharge orders (including prescriptions) in AM; arrange for home health care if indicated. Dictate discharge summary and send copy to surgeon and referring physician.
Surgical Progress Note

Surgical progress notes are written in “SOAP” format.

<table>
<thead>
<tr>
<th>Date/Time:</th>
<th>Post-operative Day Number:</th>
</tr>
</thead>
</table>

| Problem List: Antibiotic day number and hyperalimentation day number if applicable. List each surgical problem separately (e.g., status-post appendectomy, hypokalemia). |

| Subjective: | Describe how the patient feels in the patient’s own words, and give observations about the patient. Indicate any new patient complaints, note the adequacy of pain relief, and passing of flatus or bowel movements. Type of food the patient is tolerating (e.g., nothing, clear liquids, regular diet). |

<table>
<thead>
<tr>
<th>Objective:</th>
<th>Vital Signs: Maximum temperature ($T_{max}$) over the past 24 hours. Current temperature, vital signs.</th>
</tr>
</thead>
</table>

| Lab results: White count, hematocrit, and electrolytes, chest x-ray |

| Assessment and Plan: Evaluate each numbered problem separately. Note the patient’s general condition (e.g., improving), pertinent developments, and plans (e.g., advance diet to regular, chest x-ray). For each numbered problem, discuss any additional orders and plans for discharge or transfer. |
# Procedure Note

A procedure note should be written in the chart when a procedure is performed. Procedure notes are brief operative notes.

<table>

Discharge Summary

Patient's Name:
Chart Number:
Date of Admission:
Date of Discharge:
Admitting Diagnosis:
Discharge Diagnosis:
Name of Attending or Ward Service:
Surgical Procedures, Diagnostic Tests, Invasive Procedures:
Brief History and Pertinent Physical Examination and Laboratory Data:
Describe the course of the patient's disease up to the time the patient came to the hospital, and describe the physical exam and pertinent laboratory data on admission.
Hospital Course: Briefly describe the course of the patient's illness while in the hospital, including evaluation, operation, outcome of the operation, and medications given while in the hospital.
Discharged Condition: Describe improvement or deterioration of the patient's condition.
Disposition: Describe the situation to which the patient will be discharged (home, nursing home) and the person who will provide care.
Discharged Medications: List medications and instructions and write prescriptions.
Discharged Instructions and Follow-up Care: Date of return for follow-up care at clinic; diet, exercise instructions.
Problem List: List all active and past problems.
Copies: Send copies to attending physician, clinic, consultants and referring physician.

Prescription Writing

• Patient's name:
• Date:
• Drug name and preparation (eg, tablets size): Lasix 40 mg
• Quantity to dispense: #40
• Frequency of administration: Sig: 1 po qAM
• Refills: None
• Signature
Clinical Care of the Surgical Patient

James G. Jakowatz, MD
Marianne Cinat, MD

Radiographic Evaluation of Common Interventions

I. Central intravenous lines:
A. Central venous catheters should be located well above the right atrium, and not in a neck vein. Pneumothorax should be excluded by checking that the lung markings extend completely to the rib cages on both sides. An upright, expiratory x-ray may be helpful. Hemothorax will appear as opacification or a fluid meniscus on chest x-ray. Mediastinal widening may indicate great vessel injury.
B. Pulmonary artery catheters should be located centrally and posteriorly and not more than 3-5 cm from midline within the mediastinum.

II. Pulmonary tubes
A. Endotracheal tubes: Verify that the tube is located 3 cm below the vocal cords and 2-4 cm above the carina. The tip of tube should be at the level of aortic arch.
B. Tracheostomy: Verify by chest x-ray that the tube is located half way between the stoma and the carina; the tube should be parallel to the long axis of the trachea. The tube should be approximately 2/3 of width of the trachea, and the cuff should not cause bulging of the trachea walls. Check for subcutaneous air in the neck tissue and for mediastinal widening secondary to air leakage.
C. Chest tubes: A chest tube for pneumothorax drainage should be located anteriorly at the mid-clavicular line at the level of the third intercostal space or in the anterior axillary line directed toward the apex at the 4-5th intercostal space. Pleural effusions should be drained by locating the tube inferior-posteriorly at or about the level of the eighth intercostal space and directed posteriorly.
D. Mechanical ventilation: A chest x-ray should be obtained to rule out pneumothorax, subcutaneous emphysema, pneumomediastinum or subpleural air cysts. Lung infiltrates may diminish or disappear because of increased aeration of the affected lung lobe.

III. Gastrointestinal tubes
A. Nasogastric tubes: Verify that the tube is in the stomach and not coiled in the esophagus or trachea. The tip of the tube should not be near gastroesophageal junction. The standard size nasogastric tube is 14-16 French. Nasogastric tubes are used to decompress the stomach.
B. Feeding tubes are smaller in size (8-12 Fr) than nasogastric tubes. They are flexible and are frequently used for enteral nutrition. They are passed nasally through the stomach and into the duodenum or jejunum. The tip is radiopaque, and it should be located in the distal stomach. The tube may extend through the pylorus into the duodenum.
Blood Component Therapy

I. Crystalloids solutions
- Sodium is the principle component of crystalloid solutions, which is the most abundant solute in the extracellular fluid.
  - **Hypotonic solutions** include 0.45% normal saline and 0.25% normal saline. Hypotonic solutions are used as maintenance fluids in adults (0.45% NS) and infants (0.25% NS).
  - **Isotonic solutions** include normal saline (0.9% NaCl; 154 mEq Na and 154 mEq Cl) and lactated Ringers (130meq Na, 109 mEq Cl, 4 mEq K, 3 mEq Ca, lactate as a buffer). Isotonic solutions are used for acute resuscitation and volumereplacement. Approximately 3 cc of crystalloid should be given to replace each 1 cc of blood loss.
  - **Hypertonic saline** (7.5% NaCl; 1283 mEq Na, 1283 mEq Cl) is used to treat symptomatic hyponatremia. Replacement must be done slowly to prevent central pontine myelinolysis.

II. Colloid solution therapy
- Indicated for volume expansion.
  - **Albumin (5% or 25%)** is useful for hypovolemia or to induce diuresis with furosemide in hypervolemic, hypoproteinemic patients. Salt poor albumin is used in cirrhosis.
  - **Purified protein fraction (Plasmanate)** consists of 83% albumin and 17% globulin. It is indicated for volume expansion as an alternative to albumin.
  - **Hetastarch (Hespan)** consists of synthetic colloid (6% hetastarch in saline). Hespan is useful for volume expansion and raising osmotic pressure. Maximum dose is 1500 cc per 24 hours. Hetastarch may prolong the partial thromboplastin time.

III. Management of acute blood loss – red blood cell transfusions
- Hemorrhage should be controlled, and crystalloids should be infused until packed red blood cells are available to replace losses. In trauma, bleeding may require surgical control. If crystalloids fail to produce hemodynamic stability after more than 2 liters have been administered, packed red blood cells should be given.
  - If volume replacement and hemostasis stabilize the patient’s hemodynamic status, formal type and cross match of blood should be completed. In exigent bleeding, O negative, low titer blood or type specific (ABO matched) Rh compatible blood should be administered.

IV. Guidelines for blood transfusion in anemia
- Consider blood transfusion when hemoglobin is less than 8.0 gm/dL and hematocrit is less than 24%. If the patient has symptoms of anemia, such as chest pain, dyspnea, mental status changes, transfusion should be provided.

V. Blood component products
- **Packed red blood cells (PRBCs)**. Each unit provides 400 cc of volume, and each unit should raise hemoglobin by 1 gm/dL and hematocrit by 3%.
- **Platelets** are indicated for bleeding due to thrombocytopenia or thrombopathy. Each unit should raise the platelet count by 5,000-10,000 cells/μL. Platelets are usually transfused 8-10 units at a time. Dilutional thrombocytopenia occurs after massive blood transfusions. Therefore, platelet transfusion should be considered after 8-10 units of blood replacement. ABO typing is not necessary before platelets are given.
- **Fresh frozen plasma (FFP)** is used for bleeding secondary to liver disease, dilutional coagulopathy (from multiple blood transfusions), or coagulation factor deficiencies. ABO typing is required before administration of FFP, but cross matching is not required. Improvement
16 Fluids and Electrolytes

of INR/PTT usually requires 2-3 units. One unit of FFP should be administered for every 4-6 units of PRBCs. FFP contains all clotting factors except factors V and VII.

D. Cryoprecipitate contains factor VIII, and fibrinogen. It is given 8-10 units at a time. Cryoprecipitate may be necessary for massive transfusions.

E. Autologous blood. The patient donates blood within 35 days of surgery; frozen blood can be stored for up to 2 years. Autologous blood is useful in elective orthopedic, cardiac, and peripheral vascular procedures.

Fluids and Electrolytes

I. Maintenance fluid guidelines
A. Maintenance fluid requirements consist of 4 cc/kg for the first 10 kg of body weight, 2 cc/kg for the second 10 kg, and 1 cc/kg for each additional kg.
B. A 70 kg patient has a maintenance fluid requirement of approximately 125 mL/hr. Maintenance fluids used are D5½ NS with 20 mEq KCL/liter and D5 ¼ NS with 20 mEq KCL/liter in children.

II. Pediatric patients
A. Use D5 1/4 NS with 20 mEq KCL/liter.
B. 24 hour water requirement, kilogram method: For the first 10 kg body weight: 100 mL/kg/day PLUS for the second 10 kg body weight: 50 mL/kg/day PLUS for weight above 20 kg: 20 mL/kg/day. Divide by 24 hours to determine hourly rate.

III. Specific replacement fluids of specific losses
A. Gastric fluid (nasogastric tube, emesis). D5 ½ NS with 20 mEq KCL/liter. Replace equal volume of lost fluid q6h.
B. Diarrhea. DSLR with 15 mEq/liter KCL. Provide 1 liter replacement for each 1 kg or 2.2 lb of lost body weight; bicarbonate 45 mEq (½ amp) per liter may be added.
C. Bile. DSLR with 25 mEq/liter (½ amp) of bicarbonate.
D. Pancreatic. DSLR with 50 mEq/liter (1 amp) bicarbonate.

Evaluation of Postoperative Fever

I. Clinical evaluation
A. History. Fever >100.4-101 F. Determine the number of days since operation.
B. Differential diagnosis. Pneumonia, urinary tract infection, thrombophlebitis, wound infection, drug reaction. Atelectasis is the most common cause of fever less than 48 hrs after operation.
C. Dysuria, abdominal pain, cough, sputum, headache, stiff neck, joint or back pain may be present.
D. IV catheter infection (central or peripheral) is an important source of postoperative sepsis.
E. Fever pattern. Check previous day for fever patterns; spiking fevers indicate abscesses. Continuous fevers or high fevers indicate vascular involvement, such as infected prosthetic grafts or septic phlebitis from central IV lines.
F. Chills or rigors indicate bacteremia. These symptoms are usually not
associated with atelectasis or drug fevers. 

G. Fevers prior to the operation, alcohol use, allergies, and recent WBC count and differential counts should be assessed.

II. Physical Exam
A. General. Temperature, fever curve, tachycardia, hypotension. Examine all vascular access sites carefully.
B. HEENT. Pharyngeal erythema, neck rigidity.
C. Chest. Rhonchi, crackles, dullness to percussion (pneumonia), murmurs (endocarditis).
D. Abdomen. Masses, liver tenderness, Murphy’s sign (right upper quadrant tenderness with inspiration, cholecystitis); ascites. Costovertebral angle or suprapubic tenderness. Examine wound for purulence, induration, or tenderness.
E. Extremities. Infected decubitus ulcers or wounds; IV catheter tenderness (phlebitis); calf tenderness, joint tenderness (septic arthritis). Cellulitis, abscesses, perirectal abscess.

III. Laboratory evaluation. CBC, blood C&S X 2, UA, urine C&S; blood, urine, sputum, wound cultures, chest x-ray.

IV. Differential diagnosis
A. Wound infection, abscesses, intra-abdominal abscess, atelectasis, drug fever, pulmonary emboli, pancreatitis, alcohol withdrawal, deep vein thrombosis, tuberculosis, cystitis, pyelonephritis, osteomyelitis; IV catheter phlebitis, sinusitis, otitis media, upper respiratory infection, pelvic infection, cellulitis; hepatitis, infected decubitus ulcer, peritonitis, endocarditis, diverticulitis, cholangitis, carcinomas.
B. Medications associated with fever: H2 blockers, penicillins, phenytoin, sulfonamides.

V. Antibiotics should be initiated if there is any possibility of infection.

Sepsis

Sepsis is the most common cause of death in medical and surgical ICUs. Mortality ranges from 20-60%. The systemic inflammatory response syndrome (SIRS) is an inflammatory response that may be a manifestation of both sepsis and the inflammatory response that results from trauma or burns. The term “sepsis” is reserved for patients who have SIRS attributable to documented infection.

I. Pathophysiology
A. Although gram-negative bacteremia is commonly found in patients with sepsis, gram-positive infection may affect 30-40% of patients. Fungal, viral, and parasitic infections are occasionally encountered as well. Approximately 60% of patients with sepsis have negative blood cultures.
18 Sepsis

<table>
<thead>
<tr>
<th>Term</th>
<th>Definition</th>
</tr>
</thead>
<tbody>
<tr>
<td>Systemic inflammatory response syndrome (SIRS)</td>
<td>The systemic inflammatory response to a severe clinical insult manifested by ≥2 of the following conditions: Temperature &gt;38°C or &lt;36°C, heart rate &gt;90 beats/min, respiratory rate &gt;20 breaths/min or Pa CO₂ &lt;32 mmHg, white blood cell count &gt;12,000 cells/mm³, &lt;4000 cells/mm³, or &gt;10% band cells</td>
</tr>
<tr>
<td>Sepsis</td>
<td>The presence of SIRS caused by an infectious process; sepsis is considered severe if hypotension or systemic manifestations of hypoperfusion (lactic acidosis, oliguria, change in mental status) is present.</td>
</tr>
<tr>
<td>Septic shock</td>
<td>Sepsis-induced hypotension despite adequate fluid resuscitation, along with the presence of perfusion abnormalities that may induce lactic acidosis, oliguria, or an alteration in mental status.</td>
</tr>
<tr>
<td>Multiple organ dysfunction syndrome (MODS)</td>
<td>The presence of altered organ function in an acutely ill patient such that homeostasis cannot be maintained without intervention</td>
</tr>
</tbody>
</table>

B. Sources of bacteremia leading to sepsis include the urinary, respiratory and GI tracts, and skin and soft tissues (including catheter sites). The source of bacteremia is unknown in 30% of patients.

C. Escherichia coli is the most frequently encountered gram-negative organism, followed by Klebsiella, Enterobacter, Serratia, Pseudomonas, Proteus, Providencia, and Bacteroides species. Up to 16% of sepsis cases are polymicrobial.

D. Gram-positive organisms, including Staphylococcus aureus and Staphylococcus epidermidis, are associated with catheter or line-related infections. Fungemias may occur in immunocompromised patients or as superinfections in critically ill patients.

II. Clinical evaluation

A. Although fever is the most common sign of sepsis, normal body temperatures and hypothermia are common in the elderly. Tachypnea and/or hyperventilation with respiratory alkalosis may occur before the onset of fever or leukocytosis; it is often the earliest sign of sepsis.

B. Other common clinical signs of systemic inflammation or impaired organ perfusion include altered mentation, oliguria, and tachycardia.

C. In the early stages of sepsis, tachycardia is associated with increased cardiac output; peripheral vasodilation; and a warm, well-perfused appearance. As shock develops, vascular resistance continues to fall, hypotension ensues and myocardial depression progresses and results in decreased cardiac output. During the later stages of septic shock, vasoconstriction and cold extremities develop.

D. Laboratory findings. In the early stages of sepsis, arterial blood gas measurements usually reveal respiratory alkalosis. As shock ensues, metabolic acidosis—or mixed metabolic acidosis with respiratory alkalosis—becomes apparent. Hypoxemia is common.

E. Hemodynamics

1. The hallmark of early septic shock is a dramatic drop in systemic vascular resistance, which may precede a decrease in blood pressure.
2. Cardiac output rises in response to the fall in systemic blood pressure. This is referred to as the “hyperdynamic state” in sepsis. Shock results if the increase in cardiac output is insufficient to maintain blood pressure. Diminished cardiac output may also occur as systemic blood pressure falls.

III. Treatment of sepsis

A. Resuscitation. During the initial resuscitation of a hypotensive patient with sepsis, large volumes of IV fluid should be given. Initial resuscitation may require 4 to 6 L of crystalloid. Fluid infusion volumes should be titrated to obtain a pulmonary capillary wedge pressure of 10 to 20 mm Hg. Other indices of organ perfusion include oxygen delivery, serum lactate levels, arterial blood pressure, and urinary output.

B. Vasopressor and inotropic therapy is necessary if hypotension persists despite aggressive fluid resuscitation.
1. Dopamine is a first-line agent for sepsis-associated hypotension. It has combined dopaminergic, alpha-adrenergic, and beta-adrenergic activities. Begin with 5 µg/kg/min and titrate the dosage to the desired blood pressure response, usually a systolic blood pressure of greater than 90 mm Hg.
2. Epinephrine or norepinephrine infusions may be used if hypotension persists despite high dosages of dopamine (20 µg/kg/min), or if dopamine causes excessive tachycardia. These agents have alpha-adrenergic and beta-adrenergic effects and cause peripheral vasoconstriction and increased cardiac contractility.
3. Dobutamine can be added to increase cardiac output and oxygen delivery through its beta-adrenergic inotropic effects.

C. Diagnosis and management infection

1. Initial treatment of life-threatening sepsis usually consists of a third-generation cephalosporin (ceftazidime, cefotaxime, ceftriaxone), ticarcillin/clavulanic acid, or imipenem. An aminoglycoside (gentamicin, tobramycin, or amikacin) should also be included. Antipseudomonal coverage is important for hospital- or institutional-acquired infections. Appropriate choices include an antipseudomonal penicillin or cephalosporin or an aminoglycoside.

2. Methicillin-resistant staphylococci. If line sepsis or an infected implanted device is a possibility, vancomycin should be added to the regimen to cover for methicillin-resistant Staph aureus and methicillin-resistant Staph epidermidis.

3. Intra-abdominal or pelvic infections are likely to involve anaerobes; therefore, treatment should include either piperacillin/tazobactam, imipenem, or meropenem. Alternatively, metronidazole with an aminoglycoside and ampicillin may be initiated. Abscesses require drainage by surgery or interventional radiology.

4. Biliary tract infections. When the source of bacteremia is the biliary tract, piperacillin/tazobactam (Zosyn) may be used. An aminoglycoside plus clindamycin is an alternative. The predominant organisms in biliary tract infections are E coli, Klebsiella, and enterococcus.

5. **Vancomycin-Resistant Enterococcus (VRE)**
   a. An increasing number of enterococcal strains are resistant to ampicillin and gentamicin. The incidence of vancomycin-resistant enterococcus (VRE) is rapidly increasing.
   b. **Quinupristin/dalfopristin (Synercid)** is a parenteral agent active against strains of vancomycin-resistant enterococci, except E. faecium and E. faecalis.
   c. **Linezolid (Zyvox)** is an oral or parenteral agent active against vancomycin-resistant enterococci, including E. faecium and E. faecalis.

**References:** See page 108.

**Nutrition in the Surgical Patient**

I. **Nutritional requirements** are based on the patient’s nutritional needs, stress and severity of illness. Requirements are divided into non-protein calories per kilogram (npc/kg) and grams of protein per kilogram (gm protein/kg) per 24-hour period.
22 Nutrition in the Surgical Patient

</tbody>
</table>

A. Sources of non-protein calories
1. Carbohydrate solutions contain dextrose, which contains 3.4 kcal/gm
2. Lipid solutions contain 9.1 kcal/gm

B. Protein calories. Amino acid solutions contain protein in a concentration of 4 kcal/gm

II. Enteral nutrition
A. Enteral nutrition is more physiologic and technically easier to administer than parenteral nutrition. Enteral nutrition can be administered via nasogastric, nasoduodenal or nasojejunal tubes, or gastrostomy or jejunostomy tubes.

B. Continuous enteral infusion
1. Initial enteral solution infusion starts at 30 mL/hr. Increase rate by 30 mL at 4-hour intervals as tolerated until the final rate is achieved. Residual volume should be measured every 4 hours. Hold feedings for 1 hour if the residual is greater than 2 times the infusion rate.
2. Gastric/duodenal feedings: Start with full strength formula and increase the rate until the goal is achieved.
3. Jejunal feedings: Start with ¼ strength formula. Increase the rate until the goal is achieved. Once at goal rate, change to ½ strength formula for 4-8 hours, then ¾ strength formula for 4-8 hours, then full strength formula for 4-8 hours. This method allows the mucosa of the distal small bowel to adjust to the increased osmolarity of enteral formulas.

C. Bolus feedings: Give 50-100 cc enteral nutrition every 3 hours initially. Increase by 50 cc each feeding until the goal of 250-300 cc q 3-4 hours is achieved. Flush tube with 100 cc of water after each bolus.

D. Promotility agents are given to improve gastric emptying
1. Metoclopramide (Reglan) 5-10 mg PO/IV q8h OR
Total Parental Nutrition

2. Erythromycin 125 mg IV or via nasogastric tube q8h.

E. Antidiarrheal Agents
1. Loperamide (Imodium) 2-4 mg q6h.
2. Diphenoxylate/atropine (Lomotil) 2.5-5.0 mg q4-6h.

Total Parental Nutrition

I. Indications for total parenteral nutrition: Prolonged post-operative ileus, inability to take oral feedings for more than 5 days, severe malnutrition, intestinal fistula, pancreatitis. Total parenteral nutrition should be given via a central catheter because of high osmolality.

II. Standard solutions and components
A. Dextrose solutions. Various concentrations are available. One gram of dextrose yields 3.4 kcal.

<td></td>
</tr>
</tbody>
</table>

* Acetate is used in addition to chloride to help prevent hyperchloremic acidosis. One-third to one half of sodium and potassium should be supplied in the form of acetate rather than chloride.

** Calcium should be given as calcium gluconate or calcium chloride. One gram of calcium supplies 4.5 meq of calcium.

1. Other additives
   a. Multivitamins 1 amp daily
   b. Vitamin K 10 mg each week
   c. Trace elements chromium, copper, manganese, zinc, selenium

E. Ordering Total Parenteral Nutrition

1. Step One. Determine the daily non-protein calories (dextrose and lipid) and grams or protein (amino acid) that the patient needs.

   Non-protein calory requirement/kg/day = wt in kg x npc requirement/kg/d

   Protein requirement = wt in kg x protein requirement/kg/d
2. **Step Two.** Non-protein calories consist of lipids and carbohydrate (dextrose) solutions. The amount of each component should be determined. 500cc of 10% Intralipid solution will supply approximately 500 npc kcal. The patient will require the remaining non-protein calories from the dextrosem solution. If using D50, the volume of D50 = npc x 1000 cc/1700 kcal.

3. **Step Three.** Protein calories are supplied by amino acid solutions.

Vol of 7% Aminosyn = gm protein required/d x 100 cc/7 gm

4. **Step Four.** Combine the above volumes to determine total volume and rate. The dextrose and amino acid solutions are mixed together and given over 24 hours. The lipid solution is infused separately over 24 hours.

**F. Methods of delivery**

1. **Continuous infusion of the solutions** over 24 hours is the most common method of administration. The TPN solution should be initiated slowly at 40 cc/hr for the first 24 hours. The rate can then be gradually increased by 30 cc/hr every four hours until the goal rate is reached.

2. **Cyclic total parenteral nutrition 12-hour night schedule.** Taper continuous infusion in the morning by reducing the rate to half of the original rate for one hour. Further reduce the rate by half for an additional hour, then discontinue. Restart TPN in the afternoon. Taper at the beginning and end of cycle.

**G. Laboratory examinations**

1. **Baseline Labs:** CBC, electrolytes, liver function tests, prealbumin, transferrin, triglyceride level, chest x-ray for line placement

2. **Daily Labs:** Electrolytes, calcium, phosphorous until stable; glucometer checks with insulin sliding scale every 4–6 hours

3. **Weekly Labs:** CBC, electrolytes, calcium, phosphorous, liver function tests, triglyceride level (4–6 hours after completion of lipid infusion; should be maintained <200 mg/dl)

4. **Nutritional Assessment** to determine adequacy of nutritional supplementation:
   a. Prealbumin or transferrin weekly
   b. 24-hour urine for urine urea nitrogen (to calculate nitrogen balance

**III. Peripheral parenteral nutrition (PPN)** can be delivered via peripheral veins.

A. The goal of PPN is to provide enough non-protein calories to prevent catabolism and the breakdown of visceral proteins. Peripheral parenteral nutrition is not meant to create a positive nitrogen balance or anabolic state, and it should be used for short-term support only.

B. PPN usually consists of a 3% amino acid solution mixed with dextrose 20% or glycerol. Intralipids (10% or 20%) can also be given peripherally to supply extra calories.
Central Venous Catheterization

I. Indications for central venous catheter cannulation:
- Monitoring of central venous pressures in shock or heart failure;
- Management of fluid status;
- Administration of total parenteral nutrition;
- Prolonged antimicrobial therapy or chemotherapy.

II. Location of catheterization site

A. The internal jugular approach should not be used in patients with a carotid bruit, carotid stenosis, or an aneurysm.
B. The subclavian approach should be avoided in patients with emphysema or bullae.
C. The external jugular or internal jugular approach by direct cut-down may be preferable in patients with coagulopathy or thrombocytopenia.
D. If a chest tube already in place, the catheter should be placed on the same side as the chest tube.

III. Technique of insertion into the external jugular vein

A. The external jugular vein courses from the angle of the mandible to behind the middle of the clavicle, where it joins with the subclavian vein. Place patient in Trendelenburg's position, and apply digital pressure to the external jugular vein above clavicle to distend the vein. Cleanse the skin with Betadine iodine solution using sterile technique. Inject 1% lidocaine to produce a skin weal.
B. With an 18-gauge, thin-wall needle, advance the needle into the vein. Then pass a J- guidewire through the needle; the wire should advance without resistance. Remove the needle, maintaining control over the guidewire at all times. Nick the skin with a No. 11 scalpel blade.
C. With guidewire in place, pass the central catheter over the wire, and remove the guidewire after the catheter is in place. Cover the catheter hub with a finger to prevent air embolization.
D. Attach a syringe to the catheter hub, and ensure that there is free backflow of dark venous blood. Attach the catheter to an intravenous infusion at a keep open rate. Secure the catheter in place with 2-0 silk suture and tape.
E. Obtain a chest x-ray to confirm position and rule out pneumothorax. The catheter should be removed and changed within 3-4 days.

IV. Internal jugular vein cannulation.

A. Place the patient in Trendelenburg's position, and turn the patient's head to the contralateral side. Choose a location on the right or left. If lung function is symmetrical and no chest tubes are in place, the right side is preferred because of the direct path to the superior vena cava. Prepare the skin with Betadine solution using sterile technique and drape the area. Infiltrate the skin and deeper tissues with 1% lidocaine.
B. Palpate the carotid artery. Using a 22-gauge scout needle and syringe, direct the needle toward the ipsilateral nipple at a 30 degree angle to the neck. While aspirating, advance the needle until the vein is located and blood back flows into the syringe.
C. Remove the scout needle and advance an 18-gauge, thin wall, catheter-over-needle (with an attached syringe) along the same path as the scout needle. When back flow of blood is noted into the syringe, advance the catheter into the vein. Remove the needle and confirm back flow of blood.
Pulmonary Artery Catheterization 27

through the catheter and into the syringe. Remove the syringe and cover the catheter hub with a finger to prevent air embolization.

D. With the catheter in position, advance a guidewire through the catheter. The guidewire should advance easily without resistance.

E. With the guidewire in position, remove the catheter and use a No. 11 scalpel blade to nick the skin. Place the central vein catheter over the wire, holding the wire secure at all times. Pass the catheter into the vein, and suture the catheter to the skin with O silk suture. Tape the catheter in place, and connect it to an IV infusion at a keep open rate.

F. Obtain a chest x-ray to rule out pneumothorax and confirm position.

V. Subclavian vein cannulation

A. The subclavian vein is located in the angle formed by the medial 1/3 of clavicle and the first rib.

B. Position the patient supine with a rolled towel located longitudinally between the patient’s scapulae, and turn the patient’s head towards the contralateral side. Prepare the area with Betadine iodine solution, and, using sterile technique, drape the area and infiltrate 1% lidocaine into the skin and tissues.

C. Use a 16-gauge needle, with syringe attached, to puncture the mid-point of the clavicle, advancing until the clavicle bone and needle come in contact.

D. Then slowly probe down until the needle slips under the clavicle. Advance the needle slowly towards the vein until the needle enters the vein, and a back flow of venous blood enters the syringe. Remove the syringe, and cover the catheter hub with a finger to prevent air embolization.

E. With the 16-gauge catheter in position, advance a 0.89 mm x 45 cm guidewire through the catheter. The guidewire should advance easily without resistance. With the guidewire in position, remove the catheter, and use a No. 11 scalpel blade to nick the skin. Pass the dilator over the wire.

F. Place the central line catheter over the wire, holding the wire secure at all times. Pass the catheter into the vein, and suture the catheter to the skin with 2-0 silk suture, tape the catheter in place and connect to IV infusion. Obtain a chest x-ray to confirm the position of the catheter tip and rule out pneumothorax.

Pulmonary Artery Catheterization

1. Cannulate a vein using the technique above, such as the subclavian vein or internal jugular. Advance a guidewire through the cannula, and remove the cannula. Nick the skin with a number 11 scalpel blade adjacent to the guidewire, and pass a number 8 French introducer over the wire and into the vein. Connect the introducer to an IV fluid infusion at a keep open rate, and suture introducer to the skin with 2-0 silk.

2. Pass the proximal end of the pulmonary artery catheter (Swan Ganz) to an assistant for connection to a continuous flush transducer system.

3. Flush the distal and proximal ports with heparin solution, removing all bubbles, and check balloon integrity by inflating 2 cc of air. Check pressure transducer response by moving the distal tip quickly.

4. Pass the catheter through the introducer into the vein 10-20 cm, then inflate the balloon, and advance the catheter until the balloon is in or near the right atrium.
6. The correct distance to the entrance of the right atrium is determined from the site of insertion:
   Right antecubital fossa: 35-40 cm.
   Left antecubital fossa: 45-50 cm.
   Right internal jugular vein: 10-15 cm.
   Subclavian vein: 10 cm.
   Femoral vein: 35-45 cm.

7. Run a continuous monitoring strip to record pressures as the PA catheter is advanced. Advance the balloon, inflated with 0.8-1.0 cc of air, while monitoring pressures and wave forms. Advance the catheter through the right ventricle into the main pulmonary artery until the catheter enters a distal branch of the pulmonary artery and is stopped by impaction (as evidenced by a pulmonary wedge pressure wave form).

8. Do not advance catheter with balloon deflated, and do not withdraw the catheter with the balloon inflated. After placement, obtain a chest x-ray to verify that the tip of catheter is no farther than 3-5 cm from the midline, and no pneumothorax is present.

### Venous Cutdown

**Procedures**

1. Obtain a venous cutdown tray, or minor procedure tray and instrument tray with a silk suture (3-0, 4-0) and a catheter. This procedure will require sterile gloves, sterile towels/drapes, 4x4 gauze sponges, povidone-iodine solution, 5 cc syringe, 25 gauge needle, 1% lidocaine with epinephrine, adhesive tape, scissors, needle holder, hemostat, scalpel and blade, 3-O or 4-O silk suture.

2. Apply a tourniquet proximal to the site, and identify the vein. Remove the tourniquet and prep the skin with povidone-iodine solution and drape the area. Infiltrate the skin with 1% lidocaine, then incise the skin transversely.

3. Spread the incision long-wise in the direction of the vein with a hemostat and dissect adherent tissue from the vein. Lift the vein and pass two chronic or silk ties (3-0 or 4-0) behind the vein.
Arterial Line Placement

1. Obtain a 20 gauge, 1 ½-2 inch, catheter-over-needle assembly (Angiocath), arterial line setup (transducer, tubing, pressure bag containing heparinized saline), armboard, sterile dressing, 1% lidocaine, 3 cc syringe, 25 gauge needle, and 3-0 silk.

2. The radial artery should be used. Use the Allen test to verify patency of the radial artery and adequacy of ulnar artery collaterals. Place the extremity on an armboard with a gauze roll behind the wrist to maintain hyperextension.

3. Prep with povidone-iodine and drape the wrist area. Infiltrate 1% lidocaine using a 25 gauge needle. Choose a site where the artery is most superficial and as distal as possible on the wrist.

4. Palpate the artery with the left hand, and use other hand to advance a 20 gauge catheter-over-needle into the artery at a 30 degree angle to the skin. When a flash of blood is seen, hold the needle in place and advance the catheter into the artery; occlude the artery with manual pressure while pressure tubing is connected.

5. If a needle and guide-wire kit is used, advance the guidewire into the artery, and pass the catheter over the guide-wire.

6. Suture the catheter in place with 3-0 silk, and apply a dressing.

Cricothyrotomy

1. Needle cricothyrotomy
   A. Obtain a 12-14 gauge, catheter-over-needle (Angiocath or Jelco), 6-12 mL syringe, 3 mm pediatric endotracheal tube adapter, oxygen tubing, and a high flow oxygen source.
   B. Locate the cricothyroid membrane (the notch between the thyroid cartilage and cricoid cartilage). Cleanse the neck area with povidone-iodine solution, and inject 2% lidocaine with epinephrine if the patient is conscious.
   C. With a 12 or 14 gauge, catheter-over-needle assembly on the syringe, advance needle through the cricothyroid membrane at a 45 degree angle directed inferiorly. Apply back pressure on the syringe until air is aspirated.
   D. Advance the catheter and remove the needle, then attach the hub to a 3 mm endotracheal tube adapter connected to oxygen tubing.
   E. Administer oxygen at 15 liters per minute for 1-2 seconds on, then 4 seconds off. Air flow is controlled with a Y-connector or a hole in the side of the tubing.
   F. The needle cricothyrotomy should be replaced with oral endotracheal
30 Cricothyrotomy

Intubation as soon as possible. A needle cricothyrotomy should not be used for more than 45 minutes, since exhalation of CO\textsubscript{2} is inadequate.

II. Surgical cricothyrotomy

A. Obtain a #5-#7 tracheostomy tube; tracheostomy tube adapter to connect to bag-mask ventilator; povidone-iodine solution, sterile gauze pads, scalpel handle, and hemostat.

B. Clean the neck area with povidone-iodine. Locate the thyroid and cricoid cartilages; the cricothyroid membrane extends between these two cartilages.

C. Infiltrate the overlying skin with 2% lidocaine with epinephrine if the patient is conscious. Stabilize the thyroid cartilage with the left hand, and make a vertical incision through the skin and subcutaneous tissues overlying the cricothyroid membrane, avoiding the large vessels that are located laterally.

D. Make a stab incision inferiorly in the cricothyroid membrane with the point of the blade. Insert the knife handle, and rotate the handle 90 degrees to open the incision; or use a hemostat to dilate the opening. Gently insert the endotracheal tube and secure with tape. A tracheostomy tube or an endotracheal tube may be used.

E. The surgical cricothyrotomy should be replaced with a formal tracheostomy within 24 hours.

References: See page 108.
Trauma

Michael E. Lekawa, MD

Management of the Trauma Patient

I. Primary Survey of the Trauma Patient: The primary survey should identify immediate life threatening injuries.
   A. Assess airway maintenance with cervical spine protection.
   B. Assess breathing and administer assisted ventilation if required; rule out tension pneumothorax.
   C. Assess circulation and control hemorrhage.
   D. Assess disability and neurologic status (determine the level of consciousness with Glasgow Coma Scale).
   E. Exposure: Completely undress the patient and prevent hypothermia.

II. Resuscitation phase: The primary survey and resuscitation of the patient should be done simultaneously.
   A. Assess airway and alleviate obstruction. Establish a definitive airway for patients with a GCS of less than 8 or hemodynamic instability. Protect the cervical spine until fractures have been excluded.
   B. Give oxygen and manage tension pneumothorax with needle or tube thoracostomy.
   C. Control hemorrhage by direct pressure or by surgical ligation. At least 2 large bore IVs should be places, and infuse 2-3 liters of warm Ringer’s lactate solution (LR) as needed. Administer type specific or O-negative blood if the response to LR is inadequate. Send blood for type and cross and hemoglobin.
   D. If the patient has a decreased level of consciousness, treat hypoxemia and shock, and evaluate for intercranial occupying lesion.
   E. Give warm fluids, keep the room warm, and cover the patient with warm blankets. Small doses of short acting narcotics (Fentanyl) or benzodiazepines may be given as needed.

III. Ongoing assessment and treatment
   A. Change to cross matched blood when available.
   B. Monitor for coagulopathy. The PT/PTT and fibrinogen level should be monitored, and fresh frozen plasma, cryoprecipitate or platelets should be administered as indicated.
   C. A nasogastric tube should be placed for decompression of the stomach (caution if facial fracture or unstable cervical spine).
   D. Shock
      1. A Foley catheter should be placed to evaluate urine output. Adequate resuscitation is suggested by improvement in physiologic parameters such as heart rate, systolic pressure, ventilatory rate, diastolic perfusion and capillary refill, pulse oximetry, arterial blood gas, and urine output.
      2. Reassess ABCs prior to beginning secondary survey.

IV. Secondary survey
   A. Obtain an abbreviated history, including allergies, medications, past illness, last meal, event/mechanism (AMPLE history).
   B. Evaluate the completely undressed patient, front and back, and from head to toe. Evaluate each system (head and neck, chest, abdomen, perineum, musculoskeletal, vascular and neurologic).
Penetrating Abdominal Trauma

C. Obtain x-rays of the chest, cervical spine, and pelvis. Perform peritoneal lavage, and/or CT-scan as needed. Unstable patients should not be sent to the radiology department.

D. Laboratory studies: Send type and cross for six units or more of packed red blood cells; complete blood count, platelet count, creatinine, glucose, ethanol level, pregnancy test, arterial blood gasses, UA, and urine toxicology screens.

V. Treatment of shock

A. Maintain airway, breathing, and circulation (ABCs). Rapid exsanguinating injuries take precedence over other injuries, including head injuries.

B. Initial stabilization: Control external bleeding with direct external pressure. Place two 14 or 16 gauge intravenous lines and type and cross for packed red blood cells. If there is insufficient time to cross match, give type O-negative blood. Type specific blood should be given if time permits.

C. For hypotensive patients, give an initial fluid challenge of 2 liters of LR over 5-10 min or 20 ml/kg in children over 5-10 min. Assess response to initial fluid challenge by checking blood pressure and heart rate. Patients who respond with only a transient increase in blood pressure should be rechallenged with LR or blood transfusion. Blood loss may be continuing in these patients.

D. Patients who do not respond to initial fluid challenge may have had either extensive blood loss or continuing bleeding, which must be identified (chest, abdomen, extremities, pelvis). Surgical intervention should be initiated. Other causes of hypotension include tension pneumothorax and cardiac tamponade.

VI. Empiric management of coagulopathy. Consider empiric administration of 1 unit FFP for every 4 units of packed red blood cells, and consider 10 units platelets (or 1 unit of single donor platelets) per 6 units PRBC.

Penetrating Abdominal Trauma

I. Gun shot wounds

A. All abdominal gun shot wounds require exploratory laparotomy. Tangential wounds that do not penetrate the peritoneal cavity may be assessed by peritoneal lavage or laparoscopy if the wound is located on the anterior abdominal wall.

II. Stab wounds and other penetrating abdominal trauma

A. Exploratory laparotomy is required if an acute abdomen is present or if signs of visceral injury, shock, hypertension, upper or lower GI bleeding, evisceration or pneumoperitoneum is present.

B. If the patient is stable and the abdominal fascia has been penetrated or if disruption cannot be ruled out by local exploration, diagnostic peritoneal lavage (DPL) or 24 hours of serial exams should be completed.

C. Consider tetanus prophylaxis as indicated.
Blunt Abdominal Trauma

I. Physical findings of peritonitis or pneumoperitoneum on x-ray require exploratory laparotomy.

II. If the patient has a non-acute abdomen
   A. If the patient is stable with a clinically evaluable abdomen who does not undergo exploratory laparotomy, serial abdominal exams should be performed. If significant tenderness or peritoneal signs are noted, the patient should be evaluated by diagnostic peritoneal lavage, CT, or laparotomy.
   B. If the clinical evaluation is inadequate, perform diagnostic peritoneal lavage or CT-scan to rule out intra-abdominal injury.
   C. If the patient is not stable (systolic blood pressure <100 mmHg, HR >100, decreasing hemoglobin) and abdominal injury is possible, diagnostic peritoneal lavage should be done rather than CT-scan. If lavage is positive, laparotomy is required.
   D. If a CT-scan shows isolated splenic or liver injury, and the patient remains stable, the patient may be observed in the ICU. Other injuries should be assessed with laparotomy. CT-scan is less sensitive for intestinal or diaphragmatic injury.
   E. If there is a significant head injury, intoxication, or distracting injury (eg, multiple rib fractures, pelvic fracture, extremity fracture), the abdominal exam is unreliable. These patients must be evaluated by diagnostic peritoneal lavage or CT-scan.
   F. If the patient is to undergo a prolonged orthopedic or neurosurgical procedure, the abdomen should be evaluated with diagnostic peritoneal lavage or CT-scan before the procedure. A diagnostic peritoneal lavage can be done in the operating room.

III. Diagnostic peritoneal lavage
   A. Insert a nasogastric tube and Foley catheter to decompress the stomach and the bladder. Restrain or sedate the patient if necessary. Prep and drape the periumbilical region with Betadine solution and sterile towels. A site should be selected above or below umbilicus. If the patient has a pelvic fracture or if pregnant, the site should be located above the umbilicus.
   B. Infiltrate the skin and subcutaneous tissue with 1% lidocaine with epinephrine. Incise the skin with a 1.5 cm vertical incision through the subcutaneous tissue down to fascia. Use a No. 11 scalpel blade to make a 2-3 mm stab incision into the fascia. Apply traction to both sides of fascial incision with towel clips. An assistant should apply strong upward traction on clips. Dissect bluntly with a small hemostat to the peritoneum, then grasp and incise the peritoneum, and introduce a lavage catheter into the pelvis.
   C. Aspirate with a 12 cc syringe. If 10 cc of blood is returned, the lavage should be considered “grossly positive” which mandates an immediate laparotomy. If the aspirate is negative, instill 1 liter of LR or saline from a pressure bag. Periodically agitate the abdomen. When only a small amount of fluid remains in the bag, drop bag to the floor, and drain the fluid by siphon action.
   D. During the procedure, keep a sponge packed in the wound and hold the catheter in place. After at least 400 cc of fluid have been removed, clamp the tubing and withdraw the catheter. Close the fascial defect with heavy absorbable suture, and staple the skin.
Head Trauma

E. Previous abdominal surgery, morbid obesity and advanced cirrhosis are relative contraindication to diagnostic peritoneal lavage. If diagnostic peritoneal lavage is indicated, it should be done by open, rather than the closed, Seldinger technique.

IV. Criteria for a positive peritoneal lavage
A. Gross blood; red blood cell count <100,000 cells/mm$^3$ (or 5-10,000 cells/mm$^3$), white blood cell count >500 cells/mm$^3$. Presence of food particles, bile, feces, or bacteria on Gram stain. Exit of lavage fluid via a chest tube or bladder catheter.
B. Amylase >20 IU/L; alkaline phosphates >3 IU.

Head Trauma

I. Initial management of head trauma
A. Support airway, breathing, and circulation (ABCs). A cervical spine injury should be considered to be present in any patient with multisystem trauma.
B. Intravenous resuscitation solutions should consist of isotonic Ringer's lactate (LR) or normal saline (NS). Fluids should be infused until the patient is euvolemic.
C. Make an initial assessment of the patient during the primary survey (alert, voice, pain, unresponsive).
D. Perform a mini-neurologic examination and repeat frequently (GCS, motor/lateralizing signs).
E. A history, including the mechanism of injury, past medical history, drug intake, should be completed.

F. Examine the skull depressed skull fractures, Battle's sign (blood in the ear canal or ecchymosis over mastoid process), Raccoon's eyes (peri orbital ecchymosis), or rhinorrhea. If any of these signs are present, the patient requires admission and a neurosurgical consult. Nasogastric and nasotracheal intubation are contraindicated in patients with significant facial trauma because a cribiform plate fracture may be present.

II. Secondary management of head trauma

A. All patients with significant head trauma should be admitted for at least 24 hours of serial neurological exams unless Glasgow coma scale is 15 and there is only brief amnesia of events, without loss of consciousness. Such patients may be discharged with instructions if reliable observation is ensured.

B. If the Glasgow coma scale is 14 or less, or if loss of consciousness was for more than a few seconds, a head CT-scan should be obtained.

C. If the mechanism of injury was significantly violent (rollover of vehicle) or if massive upper torso trauma, or if any lateralizing neurologic deficits, a head CT-scan should be obtained.

D. If the Glasgow coma scale is less than 8 or if unequal pupils, lateralizing deficits, or open head injury, there is a high probability of a subdural, epidural, or intracerebral bleed or diffuse axonal injury. This patient requires ICU admission after obtaining a CT-scan of the head and a neurosurgical consultation.

III. Ongoing management of head trauma

A. Continually reassess ABCs, ECG, systolic blood pressure, heart rate, and pulse oximeter. Serial hemoglobin or hematocrit should be obtained.

B. Isolated head injuries rarely cause hypotension. If hypotension is present, the cause should be vigorously sought. Secondary causes of brain injury, such as hypoxia and hypotension, should be managed immediately.

C. Stress ulcer prophylaxis with H₂-blockers (ranitidine, cimetidine) or sucralfate should be administered.

D. Sequential compression stockings should be applied if the Glasgow coma scale is less than 13, or if spinal cord injury or pharmacologic paralysis is present.

E. Mannitol 1 gm/kg is used to treat elevated intracranial pressure, especially in normotensive patients with pupillary abnormalities, or lateralizing signs. Steroids are not indicated in acute head injuries. Hyperventilation may be used for short periods in select patients.

F. Open head wounds should be cleaned and repaired.

G. Tetanus prophylaxis should be given with 0.5 cc tetanus toxoid IM, with
36 Thoracic Trauma

or without tetanus lg 250 IU, IM, as indicated.

H. Patients with an abnormal head CT-scan, neurologic deficit or a sustained Glasgow coma scale less than 14 require early neurosurgery consultation.

Thoracic Trauma

I. Management of traumatic pneumothorax
   A. Give high-flow oxygen and immediately insert a chest tube. Aggressive hemodynamic and respiratory resuscitation should be initiated.
   B. Tension pneumothorax should be treated immediately with a needle thoracostomy, followed by insertion of a chest tube.

II. Technique of chest tube insertion
   A. The patient should be placed in the supine position, with involved side elevated 10-20 degrees. The arm should be abducted at 90 degrees. The usual site of insertion is the anterior axillary line at the level of the fourth intercostal space (nipple line). Cleanse the skin with Betadine iodine solution and drape the field. The intrathoracic tube distance can be estimated by the distance between the lateral chest wall and the apex of the lung. The intrathoracic tube distance should be marked with a clamp.
   B. Infiltrate 1% lidocaine into the skin, subcutaneous tissues, intercostal muscles, periosteum, and pleura using a 25-gauge needle. Use a scalpel to make a transverse skin incision, 2 centimeters wide, located over the rib just inferior to the interspace where the tube will penetrate the chest wall.
   C. A Kelly clamp should be used to bluntly dissect a subcutaneous tunnel from the skin incision, extending just over the superior margin of the rib. The nerve, artery, and vein located just below each rib should be avoided.
   D. Bluntly dissect over the rib and penetrate the pleura with the clamp, and open the pleura 1 centimeter.
   E. With a gloved finger, explore the subcutaneous tunnel, and palpitate the lung medially. Exclude possible abdominal penetration, and verify correct location within the pleural space, use a finger to remove any local pleural adhesions.
   F. Use the Kelly clamp to grasp the tip of the thoracostomy tube (36 F, Argyle, internal diameter 12 mm), and direct it into the pleural space in a posterior, superior direction for pneumothorax evacuation. Guide the tube into the pleural space until the last hole is inside the pleural space.
   G. Attach the tube to 20 cm H$_2$O of suction. Suture the tube to the skin of the chest wall using O silk. An untied, vertical, mattress suture may be placed to close the skin when the chest tube is removed in a few days.
   H. Apply Vaseline gauze, 4 x 4 gauze sponges, and elastic tape. Obtain a chest x-ray to verify correct tube placement and to evaluate re-expansion of the lung.

III. Indications for thoracotomy after trauma
   A. >1500 mL blood from chest tube on insertion.
   B. >200 mL blood/hour from chest tube thereafter (for 2-4 hours).
   C. Massive air leak such that lung will not re-expand after a properly placed and functioning chest tube has been inserted.
Tension Pneumothorax

I. Clinical signs
   A. Tension pneumothorax will manifest as severe hemodynamic and respiratory compromise, a contralaterally deviated trachea, and decreased or absent breath sounds on the involved side.
   B. Signs of tension pneumothorax may include hyperresonance to percussion on the affected side; jugular venous distention, and asymmetrical chest wall motion with respiration.

II. Radiographic findings
   A. Loss of lung markings on the ipsilateral side is commonly seen. Flattening or inversion of the ipsilateral hemidiaphragm and contralateral shifting of the mediastinum are usually present. Flattening of the cardi mediastinal contour, and spreading of the ribs on the ipsilateral side may be apparent.

III. Acute management of tension pneumothorax
   A. Place a chest tube as described above. A temporary large-bore IV catheter may be inserted at the level of the second intercostal space into the pleural space, until the chest tube is placed.

Flail Chest

I. Clinical evaluation
   A. Flail chest occurs after two or more adjacent ribs become fractured in two locations. Flail chest usually occurs secondary to severe, blunt chest injury. The fractured ribs allow a rib segment, without bony continuity with the chest wall, to move freely during breathing. Hypoxia may result from underlying pulmonary contusion.
   B. Arterial blood gases should be measured if respiratory compromise is significant. If the fracture is in the left lower rib cage, splenic injury should be excluded with CT-scan.

II. Management of flail chest
   A. Aggressive pulmonary suctioning and close observation for any signs of respiratory insufficiency or hypoxemia are recommended. Endotracheal intubation and positive-pressure ventilation is indicated for significant cases of flail chest if oxygenation is inadequate. Associated injuries, such as pneumothorax and hemothorax, should be treated with tube thoracostomy.
   B. Pain control with epidural or intercostal blockade may eliminate the need for intubation. Intubation is required if there are significant injuries with massive pulmonary contusion or poor pulmonary reserve.
   C. If mechanical ventilation is required, the ventilator should be set to assist control mode to put the flail segment at rest for several days. Thereafter, atrial of low rate, intermittent, mandatory ventilation may be attempted to check for return of flail, prior to attempting extubation.

Massive Hemothorax

I. Clinical evaluation
   A. Massive hemothorax is defined as greater than 1500 mL of blood lost into the thoracic cavity. It most commonly occurs secondary to penetrating
Cardiac Tamponade

I. Clinical evaluation
A. Cardiac tamponade most commonly occurs secondary to penetrating injuries. Cardiac tamponade can also occur when a central line penetrates the wall of the right atrium.
B. Cardiac tamponade is often manifested by Beck’s triad of venous pressure elevation, drop in the arterial pressure, and muffled heart sounds.
C. Other signs include hypovolemic shock, pulseless electrical activity (electromechanical dissociation), low voltage ECG, and enlarged cardiac silhouette on chest x-ray.
D. Kussmaul’s sign, rise in venous pressure with inspiration, may be present. Pulsus paradoxus or elevated venous pressure may be present.

II. Management
A. Pericardiocentesis or placement of a pericardial window is indicated if the patient is unresponsive to fluid resuscitation measures for hypovolemic shock.
B. All patients who have a positive pericardiocentesis (recovery of non-clotting blood) due to trauma require open thoracotomy with inspection of the myocardium and the great vessels. Cardiothoracic surgery should be consulted.
C. Intravenous fluids or blood should be given as temporizing measures on the way to the operating room.
D. Other causes of hemodynamic instability or electromechanical dissociation that may mimic cardiac tamponade include tension pneumothorax, massive pulmonary embolism, or hypovolemic shock.
E. Subxiphoid pericardial window is an equally rapid and safer procedure.
Other Life-Threatening Trauma Emergencies

I. Cardiac contusions
   A. Arrhythmias are the most common consequence of cardiac contusions. Pump failure can also occur.
   B. Treatment. The patient should receive cardiac monitoring for 24 hours or longer if arrhythmias are present. If pump failure is suspected, cardiac function should be assessed with an echocardiogram or Swan Ganz catheter. Inotropic support should be provided.

II. Pulmonary contusions
   A. Pulmonary contusions are the most common potentially fatal chest injuries. Respiratory failure and hypoxemia may develop gradually over several hours. The clinical severity of hypoxia does not correlate well with chest x-ray, however, a contusion visible on initial CHEST X-RAY predicts a need for mechanical ventilation.
   B. If pulmonary compromise is mild and there is no other injury, patients can be managed without intubation.
   C. Treatment of severe contusions, especially with multiple injuries consists of intubation, positive pressure ventilation, and PEEP.

III. Traumatic aortic transection
   A. Diagnosis of traumatic aortic transection requires a high index of suspicion after severe chest trauma.
   B. The chest x-ray may show a widened mediastinum, obscured aortic knob, and a left pleural cap. The diagnostic standard remains aortogram, although transesophageal echocardiogram and spiral CT-scan are also useful. Management consists of immediate surgical repair.

IV. Pelvic fracture
   A. Fracture of the pelvis can produce exsanguinating hemorrhage. Diagnosis is by physical examination, plain x-ray films, and CT-scan.
   B. Hemorrhage is often difficult or impossible to control at laparotomy. Most bleeding is venous, and may be decreased by external fixation of the pelvis. Arterial bleeding sometimes occurs, and requires angiographic embolization.
   C. Pelvic fractures are often associated with abdominal injury. Diagnostic peritoneal lavage can be utilized to establish the presence of internal hemorrhage, although CT-scan is preferred. Associated bladder or urethral injuries are also common.

V. Traumatic esophageal injuries
   A. Clinical evaluation
      1. Esophageal injuries are usually caused by penetrating chest injuries, severe blunt trauma to the abdomen, nasogastric tube placement, endoscopy, or by repeated vomiting (Boerheave’s syndrome).
      2. After rupture, esophageal contents leak into the mediastinum; followed by immediate or delayed rupture into the pleural space (usually on left), with resulting empyema.
      3. A high index of suspicion is required in transthoracic penetrating injuries. Transmediastinal penetrating injuries mandate a search for great vessel, tracheobronchial, and esophageal injuries.
   B. Treatment of esophageal injuries. Surgical therapy consists of primary
surgical repair of the esophagus, with drainage, or esophageal diversion in the neck and a gastrostomy. Perforated tumors should be resected. Empiric broad spectrum antibiotic therapy should be initiated.

References: See page 108.

Burns

Bruce M. Achauer, MD

Over 50,000 people are hospitalized every year for burn injuries, and more than one million people are burned each year in the US. Burn injuries cause over 5000 deaths each year in the US.

I. Initial assessment

A. An evaluation of the Airway, Breathing, and Circulation (the ABCs) should receive first priority. The history should include the time, location and circumstances of the injury, where the patient was found, and their condition. Past medical and social history, current medication usage, drug allergies, and tetanus status should be rapidly determined.

B. Smoke inhalation causes more than 50% of fire-related deaths. Patients sustaining an inhalation injury may require aggressive airway intervention. Most injuries result from the inhalation of toxic smoke; however, superheated air may rarely cause direct thermal injury to the upper respiratory tract.

C. Patients who are breathing spontaneously and at risk for inhalation injury should be placed on high-flow humidified oxygen. Patients trapped in buildings or those caught in an explosion are at higher risk for inhalation injury. These patients may have facial burns, singeing of the eyebrows and nasal hair, pharyngeal burns, carbonaceous sputum, or impaired mentation. A change in voice quality, stridorous respirations, or wheezing may be noted. The upper airway may be visualized by laryngoscopy, and the tracheobronchial tree should be evaluated by bronchoscopy. Chest radiography is not sensitive for detecting inhalation injury.

D. Patients who have suffered an inhalation injury are also at risk for carbon monoxide (CO) poisoning. The pulse oximeter is not accurate in patients with CO poisoning because only oxyhemoglobin and deoxyhemoglobin are detected. CO-oximetry measurements are necessary to confirm the diagnosis of CO poisoning. Patients exposed to CO should receive 100% oxygen using a nonrebreather face mask. Hyperbaric oxygen (HBO) therapy reduces the half-life of CO to 23 minutes.

II. Burn assessment

A. After completion of the primary survey, a secondary survey should assess the depth and total body surface area (TBSA) burned.

B. First-degree burns involve the epidermis layer of the skin, but not the dermal layer. These injuries are characterized by pain, erythema, and lack of blisters. First-degree burns are not considered in calculation of the TBSA burned.

C. Second-degree burns are subdivided into superficial and deep partial-thickness burns.

1. Superficial partial-thickness burn injury involves the papillary dermis, containing pain-sensitive nerve endings. Blisters or bullae may be present, and the burns usually appear pink and moist.
2. Deep partial-thickness burn injury damages both the papillary and reticular dermis. These injuries may not be painful and often appear white or mottled pink.

D. Full-thickness or third-degree burns involve all layers of the epidermis and dermis. They appear white or charred. These burns usually are painless because of destruction of nerve endings, but the surrounding areas are extremely painful. Third-degree burns are treated with skin grafting to limit scarring.

E. Fourth-degree burns involve structures beneath the subcutaneous fat, including muscle and bone.

F. Estimation of total body surface area burn is based upon the “rule of nines.”

Classification of Burns

- **Minor**
  - Less than 15% TBSA burns in adults or less than 10% TBSA burns in children or the elderly with less than 2% full-thickness injury

- **Moderate**
  - Partial- and full-thickness burns of 15-25% TBSA in young adults, 10-20% in children younger than 10 and adults older than 40
  - Full-thickness burns less than 10% TBSA, not involving special care area.
42 Burns

Major Burns

• Greater than 25% TBSA burns in young adults or greater than 20% TBSA in children younger than 10 and adults older than 40.
• Full-thickness burns of 10% or greater. All burns of special care areas that are likely to result in either functional or cosmetic impairment (i.e., face, hands, ears, or perineum).
• All burns complicated by inhalation injury, high-voltage electrical injury, or associated major trauma. High-risk patients include infants, the elderly, and patients with complicated medical problems.

III. Management of moderate to severe burns

A. Initial fluid resuscitation--The Parkland Formula

1. Initiation of fluid resuscitation should precede initial wound care. In adults, IV fluid resuscitation is usually necessary in second- or third-degree burns involving greater than 20% TBSA. In pediatric patients, fluid resuscitation should be initiated in all infants with burns of 10% or greater TBSA and in older children with burns greater than 15% or greater TBSA.

2. Two large-bore IV lines should be placed. Lactated Ringer’s solution is the most commonly used fluid for burn resuscitation.

3. The Parkland formula is used to guide initial fluid resuscitation during the first 24 hours. The formula calls for 4 cc/kg/TBSA burn (second and third degree) of lactated Ringer’s solution over the first 24 hours. Half of the fluid should be administered over the first eight hours post burn, and the remaining half should be administered over the next 16 hours. The volume of fluid given is based on the time elapsed since the burn.

4. A urine output of 0.5-1.0 mL/kg/h should be maintained. Patients with significant burns should have a Foley catheter inserted in order to monitor urine output.

B. A nasogastric (NG) tube should be placed in patients with burns involving 20% or more TBSA in order to prevent gastric distention and emesis associated with a paralytic ileus.

C. Antibiotics is not generally recommended for initial management of burns but may be considered in the young child with suspected streptococcal infection.

D. Laboratory studies should include a complete blood count, electrolytes, serum glucose, BUN, and creatinine. Additional laboratory studies may include an ABG, CO Hb level, urinalysis, urine myoglobin, coagulation studies, blood type and screen, toxicology screen, serum ethanol level, and serum protein. Patients with known heart disease or patients at risk for cardiac complications require a baseline ECG. A chest x-ray and other radiographs should be obtained as indicated.

E. Pain control. After completion of the primary and secondary survey, priority should be given to pain management. Morphine 0.1 mg/kg IV or meperidine (Demerol) 1-2 mg/kg IV should be used on an hourly basis.

F. Complications associated with eschar formation may occur in circumferential, deep partial- or full-thickness burns. Emergent escharotomy can relieve life-or limb-threatening constrictions caused by circumferential burns.

G. Tetanus toxoid (0.5 cc) should be administered as indicated. If the wound is >50% of the body surface area, 250 units of tetanus immune
globulin should also be administered.

H. Burn center transfer. Most burn patients require only outpatient care. Most moderate burns and all major burns require hospitalization. Burns involving more than 15% of the total body surface area in adults, or more than 10% in children, should be transferred to a burn center. Patients with other severe injuries, extremes of age or inhalation injury should also be admitted to a burn center.

IV. Management of minor burns

A. Home wound care, pain medication, and active range-of-motion exercises should be prescribed. Some patients require physical therapy.

B. Tetanus status should be assessed. The burn wound should be cleansed with a mild soap and water or saline. Devitalized tissue or ruptured blisters should be débrided using aseptic technique. Unruptured blisters should be left intact.

C. Most outpatient burns are managed with closed dressings applied with topical antibiotics. A thin layer of sulfadiazine 1% (Silvadene) cream can be applied to a sterile gauze using a tongue blade, and then the gauze should be applied to the burn. Dressings are changed daily or twice daily and can be removed under running water.

D. Silver sulfadiazine should be avoided in patients with allergies to sulfonamides, pregnant women approaching or at term, or in newborn infants during the first two months of life. Silvadene therapy may rarely cause a transient leukopenia and staining of sun-exposed skin.

References: See page 108.
44 Burns
Airway Management and Intubation

Orotracheal intubation:

- **Endotracheal tube size (interior diameter):**
  - Women 7.0-9.0 mm
  - Men 8.0 -10.0 mm.

1. Prepare functioning suction apparatus. Have bag and mask apparatus setup with 100% oxygen; and ensure that the patient can be adequately bag ventilated and that suction apparatus is available.

2. If sedation and/or paralysis is required, consider rapid sequence induction as follows:
   - Fentanyl (Sublimaze) 50 mcg increments IV (1 mcg/kg) with:
     - Midazolam hydrochloride (Versed) 1 mg IV q2-3 min, max 0.1-0.15 mg/kg; 2-5 mg IV doses q1-4h prn followed by:
     - Succinylcholine (Anectine) 0.6-1.0 mg/kg, at appropriate intervals.
   
   **Note:** These drugs may cause vomiting; therefore, cricoid cartilage pressure should be applied during intubation (Sellick maneuver).

3. Position the patient’s head in “sniffing” position with head flexed at neck and extended. If necessary elevate the head with a small pillow.

4. Ventilate the patient with a bag mask apparatus and hyperoxygenate with 100% oxygen.

5. Hold endoscope handle with left hand, and use right hand to open the patient’s mouth. Insert blade along the right side of mouth to the base of tongue, and push the tongue to the left. If using curved blade, advance to the vallecula (superior to epiglottis), and lift anteriorly, being careful not to exert pressure on the teeth. If using a straight blade, place it beneath the epiglottis and lift anteriorly.

6. Place endotracheal tube (ETT) into right corner of mouth and pass it through the vocal cords; stop just after the cuff disappears behind the vocal cords. If unsuccessful after 30 seconds, stop and resume bag and mask ventilation before reattempting. If necessary, use stilette to maintain the shape of the ETT; remove stilette after intubation. Application of lubricant jelly at the balloon facilitates passage through the vocal cords.

7. Inflate cuff with syringe, keeping cuff pressure .20 cm H₂O and attach the tube to an Ambu bag or ventilator. Confirm bilateral, equal expansion of the chest and equal bilateral breath sounds. Auscultate the abdomen to confirm that the ETT is not in the esophagus. If there is any question about proper ETT location, repeat laryngoscopy with tube in place to be sure it is located endotracheal; remove tube immediately if there is any doubt about proper location. Secure the tube with tape and note centimeter mark at the mouth. Suction the oropharynx and trachea.

8. Confirm proper tube placement with a chest X-ray. The tip of the ETT should be between the carina and thoracic inlet, or level with the top of the aortic notch.
Ventilator Management

I. Indications for Ventilatory Support:
Respirations >35, vital capacity <15 mL/kg, negative inspiratory force >-25, pO2 <60 on 50% O2, pH <7.2, pCO2 >55, severe hypercapnia, hypoxia, severe metabolic acidosis.

II. Initiation of ventilatory support
A. Intubation
1. Prepare suction apparatus, laryngoscope, endotracheal tube. Clear airway and place oral airway, then hyperventilate with bag and mask attached to high flow oxygen.
2. Midazolam (Versed) 1-2 mg IV boluses until sedated. 2-5 mg IV doses q1-4h prn.
3. Intubate, inflate cuff, ventilate with bag, auscultate chest, and suction trachea.
B. Initial orders. FiO2 = 100%, PEEP = 3-5 cm H2O, assist control 8-14 breaths/min, tidal volume = 800 mL (10-15 mL/kg ideal body weight), set rate so that minute ventilation (VE) is approximately 10 L/min. Alternatively, use intermittent mandatory ventilation mode with tidal volume and rate to achieve near-total ventilatory support. Consider pressure support in addition to IMV at 5-15 cm H2O.
C. ABG should be obtained in 30 min, CHEST X-RAY for tube placement, measure cuff pressure q8h (maintain >20 mmHg), pulse oximeter, arterial line, or monitor end tidal CO2. Maintain oxygen saturation >90-95%.
D. Ventilator management
1. Decreased minute ventilation. Evaluate patient and rule out complications (endotracheal tube malposition, cuff leak, excessive secretions, bronchospasms, pneumothorax, worsening pulmonary disease, sedative drugs, pulmonary infection). Readjust ventilator rate to maintain mechanically assisted minute ventilation of 10 L/min. If peak airway pressure (AWP) is >45 cm H2O, decrease tidal volume to 7-8 mL/kg (with increase in rate if necessary) or decrease ventilator flow rate.
2. Arterial saturation <94% and pO2 >100. Reduce FiO2 (each 1% decrease in FiO2 reduces pO2 by 7 mmHg); once FiO2 is <60%, PEEP may be reduced by increments of 2 cm H2O until PEEP is 3-5 cm H2O. Maintain O2 saturation of >90% (pO2 >60).
3. Arterial saturation <90% and pO2 <60, increase FiO2 up to 60-100%, then consider increasing PEEP by increments of 3-5 cm H2O (PEEP >10 requires a PA catheter). Add additional PEEP until oxygenation is adequate with an FiO2 of <60%.
4. Excessively low pH (pH <7.33): Increase rate and/or tidal volume. Keep peak airway pressure <40-50 cm H2O if possible.
5. Excessively high pH (>7.48): Reduce rate and/or tidal volume to lessen hyperventilation. If patient is breathing rapidly above ventilator rate, sedate patient.
6. Patient “fighting” ventilator: Consider intermittent mandatory ventilation or spontaneous intermittent mandatory ventilation mode, or add sedation with or without paralysis (exclude complications or other causes of agitation). Paralytic agents should not be used without concurrent amnesia and/or sedation.
7. Sedation
   a. Midazolam (Versed) 0.05 mg/kg IV x1, then 0.02-0.1 mg/kg/hr IV infusion. Titrate in increments of 25-50%.
Epistaxis

Roger Crumley, MD

Almost all persons have experienced a nosebleed at some time, and most nosebleeds resolve without requiring medical attention. Prolonged epistaxis, however, can be life-threatening, especially in the elderly or debilitated.
48 Epistaxis

I. Pathophysiology

A. Anterior epistaxis. In the anterior two thirds of the nose, is usually visible on the septum and is the most common type of epistaxis. The anterior portion of the septum has a rich vascular supply known as Kiesselbach's plexus or Little's area, and most epistaxis originates in this region. Anterior bleeding can often be stopped by pinching the cartilaginous part of the nose.

B. Posterior epistaxis from the posterior third of the nose accounts for 10% of nosebleeds. Bleeding is profuse because of the larger vessels in that location. It usually occurs in older patients, who have fragile vessels because of hypertension, atherosclerosis, coagulopathies, or weakened tissue. Posterior bleeds require aggressive treatment and hospitalization.

II. Causes of epistaxis

A. Trauma. Nose picking, nose blowing, or sneezing can tear or abrade the mucosa and cause bleeding. Other forms of trauma include nasal fracture and nasogastric and nasotracheal intubation.

B. Desiccation. Cold, dry air and dry heat contribute to an increased incidence of epistaxis during the winter.

C. Irritation. Upper respiratory infections, sinusitis, allergies, topical decongestants, and cocaine sniffing may cause bleeding.

D. Less common causes of anterior epistaxis include Wegener's granulomatosis, mid-line destructive disease, tuberculosis, syphilis, and tumors. Epistaxis is exacerbated by coagulopathy, blood dyscrasias, thrombocytopenia, or anticoagulant medication (NSAIDs, warfarin), hepatic cirrhosis, and renal failure.

E. Hypertension complicates active bleeding by promoting rigid arteries, and arteriosclerosis weakens vessels.

III. Clinical evaluation of epistaxis

A. Hemodynamic evaluation for tachycardia, hypotension, or light-headedness should be completed immediately. Hypovolemic patients should be resuscitated with fluids and packed red blood cells.

B. After stabilization, the site, cause, and amount of bleeding should be determined. Most patients do not require resuscitation. Posterior epistaxis in an elderly and debilitated patient can be life-threatening.

C. Determine the side of bleeding. Unilateral nose bleeding suggests anterior epistaxis in Kiesselbach's plexus. Bilateral bleeding suggests posterior epistaxis caused by overflow around the posterior septum.

D. Determine whether epistaxis is anterior or posterior: When the patient is upright, blood drains primarily from the anterior part of the nose in anterior bleeding, or it drains from the nasopharynx in posterior bleeding.

E. Assess the duration of the nosebleed and any inciting incident (eg, trauma). Swallowed blood from epistaxis may cause melena. Hypertension, bleeding disorders, diabetes, alcoholism, liver disease, pulmonary disease, cardiac disease and arteriosclerosis should be assessed.

F. Medications including aspirin, NSAIDs, warfarin, nasal sprays, and oxygen via nasal cannula should be sought.

G. Blood tests. Hematologic tests include CBC, platelet count, INR, partial thromboplastin time, and blood type and cross. The hematocrit does not immediately drop in acute hemorrhage.

IV. Localization of the site of bleeding

A. Sedation. When sedation is required, midazolam (Versed), 1-2 mg IV in adults and 0.035-0.2 mg/kg IV in children is recommended;
overmedication may threaten the cough reflex which protects the airway.

B. Drape the patient, and furnish an emesis basin. Keep the patient sitting upright or leaning forward. A gown, gloves, mask, and protective eyewear should be worn because patients may inadvertently cough blood.

C. A nasal speculum and a suction apparatus with a #10 Frazier tip are used to aspirate blood from the nose and oropharynx. A bright headlight should be used.

D. Anesthesia and vasoconstriction: A cotton-tipped applicator or cotton pledget is used to apply a topical anesthetic (eg, 1% tetracaine or 4% lidocaine) and a topical vasoconstrictor (eg, 1% ephedrine, 1% phenylephrine, or 0.05% oxymetazoline) to the entire nasal mucosa. If a bleeding site is observed, press the vasoconstrictor applicator directly to that site.

E. Visualization of bleeding site

1. The nasal speculum should be used to localize active bleeding. Kiesselbach’s plexus and the inferior turbinate are the most frequent sites of bleeding.

2. Posterior bleeding may be located by applying suction; when the suction tip is at the site of bleeding, blood will no longer well up.

V. Management of hemorrhage

A. Anterior septal hemorrhage can sometimes be stopped by nose pinching alone and by having the patient sit upright. If bleeding continues, application of the topical anesthetic and vasoconstrictor may stop it.

B. Cauterization

1. Bleeding sites that can be visualized should be cauterized with silver nitrate sticks; they work best in a dry field.

2. The septum should not be cauterized bilaterally at the same level because cartilaginous necrosis and septal perforation may result.

C. Hemostatic agents. Application of a hemostatic material (eg, microfibrillar collagen or oxidized regenerated cellulose) to the bleeding site may be useful. These products do not require removal because they dissolve in the nose after several days. The patient should lubricate the nose regularly with saline nasal spray and to use bacitracin ointment tid.

D. Packing. Gauze packing or a sponge pack applied to the anterior portion of the nose may be used as a tamponade for uncontrolled bleeding sites. These packs stay in place for 5 days.

E. Anterior nasal pack

1. The pack consists of 72 inches of half-inch gauze impregnated with antibiotic ointment. Topical anesthesia is necessary.

2. Use the nasal speculum to open the vestibule vertically. With the bayonet forceps, grasp the gauze approximately 10 cm from the end; place layers along the floor of the nose all the way back to the nasopharynx.

3. An oral broad-spectrum antibiotic, such as cephalaxin (Keflex), 500 mg orally every 6 hours, is given while the pack is in place to prevent secondary sinusitis or toxic shock syndrome. The pack is removed after 5 days.

F. Sponge pack

1. This dry, compressed sponge is lubricated with an antibiotic ointment, then placed into the nasal cavity.

2. Once moistened with blood or saline, the sponge expands, filling the nasal cavity and exerting gentle pressure on the bleeding site.
50 Epistaxis

G. Posterior pack
1. Posterior bleeding requires a posterior pack, and the patient should be admitted to the hospital. The posterior pack requires a sphenopalatine block and topical anesthetic.
2. The posterior pack is made by sewing together two tonsil tampons with 0-silk, leaving two 8-inch tails, and lubricating the tampons with antibiotic ointment.
3. Place a tight anterior gauze pack, and tie the tails around one or two dental rolls to stabilize the tampons.

H. Balloon pack
1. An effective alternative to the tampon posterior pack is a 14-French, 30-mL balloon Foley catheter.
2. Use the same anesthetic as for the tampon posterior pack, and cover the balloon with antibiotic ointment, and insert through the nostril until the tip can be seen in the nasopharynx.

Acute Abdomen

Disorders of the Alimentary Tract

Russell A. Williams, MD
I. James Sarfeh, MD
S.E. Wilson, MD

Acute Abdomen

I. Clinical evaluation of abdominal pain
   A. Onset and duration of the pain
      1. The duration, acuity, and progression of pain should be assessed, and
         the exact location of maximal pain at onset and at present should be
         determined. The pain should be characterized as diffuse or localized.
         The time course of the pain should be characterized as either constant,
         intermittent, decreasing, or increasing.
      2. Acute exacerbation of longstanding pain suggests a complication of
         chronic disease, such as peptic ulcer disease, inflammatory bowel
         disease, or cancer. Sudden, intense pain often represents an
         intraabdominal catastrophe (eg, ruptured aneurysm, mesenteric
         infarction, or intestinal perforation). Colicky abdominal pain of intestinal
         or ureteral obstruction tends to have a gradual onset.
   B. Pain character
      1. Intermittent pain is associated with spasmodic increases in pressure
         within hollow organs.
      2. Bowel ischemia initially causes diffuse crampy pain due to spasmodic
         contractions of the bowel. The pain becomes constant and more
         intense with bowel necrosis, causing pain out of proportion to physical
         findings. A history of intestinal angina can be elicited in some patients.
      3. Constant pain. Biliary colic from cystic or common bile duct
         obstruction usually is constant. Chronic pancreatitis causes constant
         pain. Constant pain also suggests peritoneal inflammation,
         mucosal inflammatory conditions, or neoplasms.
      4. Appendicitis initially causes intermittent periumbilical pain. Gradually
         the pain becomes constant in the right lower quadrant as peritoneal
         inflammation develops.
   C. Associated symptoms
      1. Constitutional symptoms (eg, fatigue, weight loss) suggests
         underlying chronic disease.
      2. Gastrointestinal symptoms
         a. Anorexia, nausea and vomiting are commonly associated with
            acute abdominal disorders. The frequency, character, and timing of
            these symptoms in relation to pain and time of the last flatus or stool
            should be determined.
         b. Constipation, obstipation, crampy pain and distention usually
            predominate in distal small-bowel and colonic obstruction. Paralytic
            ileus causes constipation and distention.
         c. Diarrhea is suggestive of gastroenteritis or colitis but may also be
            seen in partial small-bowel obstruction or fecal impaction.
         d. Small amounts of bleeding may accompany esophagitis,
            diverticulitis, inflammatory bowel disease, and left colon cancer.
            Right colon cancers usually present with occult blood loss. Severe
abdominal pain accompanied by melena or hematochezia suggests ischemic bowel.
e. Jaundice with abdominal pain usually is caused by biliary stones.
Obstruction of the common bile duct by cancer may also cause pain and jaundice.

3. Urinary symptoms. Urinary tract infections may cause pain in the lower abdomen (cystitis) or flanks (pyelonephritis). Urinary tract infections are characterized by dysuria, frequency, and cloudy urine.

4. Recent menstrual and sexual history should be determined in women with acute abdominal pain.
a. Menstrual cycle. Lower abdominal pain and a missed or irregular menses in a young woman suggests ectopic pregnancy. Pelvic inflammatory disease tends to cause bilateral lower abdominal pain. Ovarian torsion may cause intense, acute pain and vomiting. Chronic pain at the onset of menses suggests endometriosis.
b. Pregnancy. Ectopic pregnancy occurs in the first trimester. Threatened abortion, ovarian torsion, or degeneration of a uterine fibroid also may cause acute pain in women.

D. Medications
1. Nonsteroidal anti-inflammatory drugs predispose to ulcer disease.
2. Antibiotic therapy may obscure the signs of peritonitis. Patients with abdominal pain and diarrhea who have received antibiotics may have pseudomembranous colitis.
3. Anticoagulants. Warfarin therapy predisposes to retroperitoneal or intramural intestinal hemorrhage.
4. Thiazide diuretics may rarely cause pancreatitis.

E. Surgical history. Small bowel obstruction is often caused by postoperative adhesions.

II. Physical examination
A. General appearance. Peritonitis is suggested by shallow, rapid breathing and the patient often will lie still with knees flexed to minimize peritoneal stimulation. Patients may be pale or diaphoretic. Cachexia may indicate malignancy or chronic illness.

B. Fever suggests an inflammatory or infectious etiology. Tachycardia and tachypnea may be caused by pain, hypovolemia, or sepsis. Hypothermia and hypotension often suggest an infectious process. Pneumonia and myocardial infarction may occasionally cause pain that is felt in the abdomen.

C. Abdominal examination
1. Inspection. Surgical scars should be noted. Distention suggests obstruction, ileus, or ascites. Venous engorgement of the abdominal wall suggests portal hypertension. Masses or peristaltic waves may be visible. Hemothorax may cause bluish discoloration of the umbilicus (Cullen's sign). Retroperitoneal bleeding (e.g., from hemorrhagic pancreatitis) can cause flank ecchymoses (Turner's sign).
3. Palpation
   a. Palpation should be gently started at a point remote from the pain. Muscle spasm, tympany or tenderness, masses and hernias should be sought.
   b. Peritoneal signs. Rigidity is caused by reflex spasm of the abdomin-
Acute Abdomen

inal wall musculature from underlying inflamed parietal peritoneum. Stretch and release of inflamed parietal peritoneum causes rebound tenderness.

c. Common signs
(1) Murphy’s sign. Inspiratory arrest from palpation in the right upper quadrant occurs when an inflamed gallbladder descends to meet the examiner’s fingers.
(2) Obturator sign. Suprapubic tenderness on internal rotation of the hip joint with the knee and hip flexed results from inflammation adjacent to the obturator internus muscle.
(3) Iliopsoas sign. Extension of the hip elicits tenderness in inflammatory disorders of the retroperitoneum.
(4) Rovsing’s sign. Referred, rebound tenderness in the lower quadrant suggests appendicitis.

D. Rectal and pelvic examination
1. Digital examination of the rectum may detect cancer, fecal impaction, or pelvic appendicitis. Stool should be checked for gross or occult blood.
2. Pelvic examination. Vaginal discharge should be noted and cultured. Masses and tenderness should be sought bimanually. Adnexal or cervical motion tenderness indicate pelvic inflammatory disease.

III. Laboratory evaluation
A. Leukocytosis or a left shift on differential cell count are non-specific findings for infection. Leukopenia may be present in sepsis. The hematocrit can detect anemia due to occult blood loss from cancer. The hematocrit may be elevated with plasma volume deficits.
B. Electrolytes. Metabolic alkalosis occurs after persistent vomiting. Metabolic acidosis occurs with severe hypovolemia or sepsis.
C. Urinalysis. Bacteriuria, pyuria, or positive leukocyte esterase suggest urinary tract infection. Hematuria suggests urolithiasis.
D. Liver function tests. High transaminases with mild to moderate elevations of alkaline phosphatase and bilirubin suggests acute hepatitis. High alkaline phosphatase and bilirubin and mild elevations of transaminases suggests biliary obstruction.
E. Pancreatic enzymes. Elevated amylase and lipase indicates acute pancreatitis. Hyperamylasemia also may occur in bowel infarction and perforated ulcer.
F. Serum beta-human chorionic gonadotropin is required in women of childbearing age with abdominal pain to exclude ectopic gestation.

IV. Radiography
A. Plain abdominal films
(1) Acute abdomen series includes an upright PA chest, plain abdominal film (“flat plate”), upright film, and a left lateral decubitus view of the abdomen.
(2) Bowel obstruction
   a. Small bowel obstruction may cause multiple air-fluid levels with dilated loops of small intestine, associated with minimal colonic gas.
   b. Colonic obstruction causes colonic dilation which can be distinguished from small intestine by the presence of haustral markings and absence of valvulae conniventes.
(3) Free air is seen on the upright chest x-ray under the hemidiaphragms. Intestinal perforation is the most common cause of free air. A recent laparotomy may also cause free air.
Appendicitis

4. Stones and calcifications. Ninety percent of urinary stones are radiopaque. Only 15% of gallstones are visible on plain film. A fecalith in the right lower quadrant may suggest appendicitis. Vascular calcification may be visible in abdominal aneurysm.

B. Ultrasonography is useful for evaluation of biliary colic, cholecystitis, or female reproductive system disorders.

C. Computed tomography with or without oral and/or rectal contrast may help in evaluating the acute abdomen in the following situations:
1. Unobtainable or highly atypical history or physical examination
2. History of intraabdominal cancer
3. Abdominal pain and fever in the immediate postlaparotomy period
4. Acute pain superimposed on a history of chronic abdominal complaints
5. A stable patient with suspected leaking abdominal aneurysm

References: See page 108.

Appendicitis

About 10% of the population will develop acute appendicitis during their lifetime. The disorder most commonly develops in the teens and twenties. Appendicitis is caused by appendiceal obstruction, mucosal ischemia, infection, and perforation.

I. Diagnosis of appendicitis

A. Clinical presentation. Early appendicitis is characterized by progressive midabdominal discomfort, unrelieved by the passage of stool or flatus. Ninety percent of patients are anorexic, 70% have nausea and vomiting, and 10% have diarrhea. The pain migrates to the right lower quadrant after 4-6 hours. Peritoneal irritation is associated with pain on movement.

B. Physical examination
1. Mild fever and tachycardia are common in appendicitis.
2. Abdominal palpation should begin away from the right lower quadrant. Point tenderness over the right lower quadrant is the most definitive finding. Pain in the right lower quadrant during palpation of the left lower quadrant (Rovsing’s sign) indicates peritoneal irritation. The degree of direct tenderness and rebound tenderness should be assessed. The degree of muscular resistance to palpation reflects the severity of inflammation. Cutaneous hyperesthesia often overlies the region of maximal tenderness.
3. Psoas sign. With the patient lying on the left side, slow extension of the right hip causes local irritation and pain. A positive psoas sign indicates retroperitoneal inflammation.
4. Obturator sign. With the patient supine, passive internal rotation of the flexed right hip causes hypogastric pain.
5. Rectal examination should evaluate the presence of localized tenderness or an inflammatory mass in the pelvis.
6. Pelvic examination, in women, should be completed to assess cervical motion tenderness and to evaluate the presence of adnexal tenderness.
7. The appendix usually is found at McBurney’s point (two-thirds of the distance from the umbilicus to the anterior superior iliac spine).
8. Diarrhea, urinary frequency, pyuria, or microscopic hematuria may suggest a retrocecal appendix, causing irritation of adjacent structures.
Appendicitis

C. Laboratory evaluation
1. Leukocyte count greater than 11,000 cells/ul with polymorphonuclear cell predominance is common in children and young adults.
2. Urinalysis is abnormal in 25% of patients with appendicitis. Pyuria, albuminuria, and hematuria are common. Bacteria suggest urinary tract infection. Hematuria suggests urolithiasis.
3. Serum pregnancy test should be performed in women of childbearing age. A positive test suggests an ectopic pregnancy.

D. Radiologic evaluation
1. Abdominal x-rays. An appendicolith can be seen in only one-third of children and one-fifth of adults with appendicitis. An appendiceal mass can indent the cecum, and tissue edema can cause loss of peritoneal fat planes around the psoas muscle and kidney.
2. Ultrasonography. Findings associated with appendicitis include wall thickening, luminal distention, lack of compressibility, abscess formation, and free intraperitoneal fluid.

II. Differential diagnosis
A. Gastrointestinal diseases
1. Gastroenteritis is characterized by nausea, emesis prior to the onset of abdominal pain, malaise, fever, and poorly localized abdominal pain and tenderness. The WBC count is less frequently elevated.
2. Meckel’s diverticulitis may mimic appendicitis.
3. Perforated peptic ulcer disease, diverticulitis, and cholecystitis can present similarly to appendicitis.

B. Urologic diseases
1. Pyelonephritis is associated with high fever, rigors, and costovertebral pain and tenderness. Diagnosis is confirmed by urinalysis.
2. Ureteral colic. Renal stones cause flank pain radiating into the groin. Tenderness is usually minimal and hematuria is present. The intravenous pyelogram is diagnostic.

C. Gynecologic diseases
1. Pelvic inflammatory disease (PID). The onset of pain in PID usually occurs within 7 days of menstruation. Cervical motion tenderness, a white vaginal discharge, and bilateral adnexal tenderness suggest PID. Ultrasound can help distinguish PID from appendicitis.
2. Ectopic pregnancy. A pregnancy test should be performed in all female patients of childbearing age presenting with abdominal pain. Ultrasonography is diagnostic.
3. Ovarian cysts can cause sudden pain by enlarging or rupturing. The cysts are detected by transvaginal ultrasonography.
4. Ovarian torsion. The ischemic ovary often can be palpated on bimanual pelvic examination. The diagnosis is confirmed by ultrasonography.

References: See page 108.
Appendectomy Surgical Technique

I. Preoperative preparation
A. Intravenous isotonic fluid replacement should be initiated to achieve good urinary output and to correct electrolyte abnormalities. Nasogastric suction should be initiated if the patient is vomiting or if peritonitis is present.
B. Fever is treated with acetaminophen. Broad-spectrum antibiotic coverage is initiated preoperatively. Antibiotic therapy should cover gram-negative and anaerobic organisms (Cefotan or Zosyn).

II. Surgical technique
A. After induction of anesthesia, place an incision over any appendiceal mass if palpable. If no mass is present, make a transverse skin incision over McBurney’s point, located two thirds of the way between the umbilicus and anterior superior iliac spine. A transverse incision allows easy extension medially for greater exposure. Diffuse peritonitis should be explored through a midline incision.
B. Incise the subcutaneous tissues in the line of the transverse incision, and incise the external oblique aponeurosis in the direction of its muscle fibers. Spread the muscle with a Peon hemostat.
C. Incise the internal oblique fascia and spread the incision in the direction of its fibers. Sharply incise the transversus abdominis muscle, transversalis fascia, and peritoneum. Note the presence and characteristics of peritoneal fluid, and send purulent fluid for Gram’s stain and aerobic and anaerobic culture.
D. Identify the base of the cecum by the converging taeniae coli, and raise the cecum, exposing the base of the appendix. Hook an index finger around the appendix, and gently break down any adhesions to adjacent tissues. Use gauze packing to isolate the inflamed appendix, and stabilize the appendix with a Babcock forceps.
E. Apply two clamps to the mesoappendix, then divide the mesoappendix between the clamps, then firmly ligate below the clamps with 000 silk or polyglycolic acid sutures. Apply an encircling purse-string suture of 000 silk at the end of the mesoappendix about 0.8 cm from the base of the appendix. Place a hemostat at the proximal base of the appendix, and crush the appendix. Remove the hemostat and reapply it to the appendix distal to the crush. Use an 0 chromic catgut suture to ligate the crushed area below the hemostat.
F. Transect the appendix against the clamp. Invert the stump into the cecum with the purse-string suture, and tie the purse-string suture, burying the stump. Irrigate the peritoneum with normal saline, and examine the mesoappendix and abdominal wall for hemostasis. Close the peritoneum with continuous 000 catgut suture.
G. Close the internal oblique and transversus abdominis with interrupted 0 chromic catgut. Close the external oblique as a separate layer. Close the skin and subcutaneous tissues. A soft rubber Penrose drain should be placed if perforation has occurred. It should be brought out through a stab incision in the lateral abdominal wall or through the lateral end of the incision.
H. If the appendix is normal on inspection (5-20% of explorations), it should be removed, and alternative diagnoses should be investigated. The cecum, sigmoid colon, and ileum should be inspected, and mesenteric lymphadenopathy should be sought. Ovaries and fallopian tubes should be inspected for PID, ruptured cysts, or ectopic pregnancy. Bilious
III. Intravenous antibiotics

A. Antibiotic prophylaxis should include coverage for bowel flora, including aerobes and anaerobes. Cefotetan (Cefotan), 1 gm IV q12h, or piperacillin/tazobactam (Zosyn), 4.5 gm IV q6h, should be given before the operation and discontinued after two doses postoperatively.

B. If perforation has occurred, IV antibiotics should be continued for 5-10 days. Check culture on the third postoperative day and change antimicrobials if a resistant organism is present.

References: See page 108.

Hernias

A hernia is an abnormal opening in the abdominal wall, with or without protrusion of an intrabdominal structure. A hernia develops in 5% of men during their lifetime. The most common groin hernia in males or females is the indirect inguinal hernia. Femoral hernias are more common in females than in males.

I. Inguinal hernias

A. Indirect hernia sacs pass through the internal inguinal ring lateral to the inferior epigastric vessels and lie within the spermatic cord. Two-thirds of inguinal hernias are indirect

B. Direct hernias occur when viscera protrude through a weak area in the posterior inguinal wall. The base of the hernia sac lies medial to the inferior epigastric vessels, through Hesselbach's triangle, which is formed by the inferior epigastric artery, the lateral edge of the rectus sheath, and the inguinal ligament.

C. Combined (pantaloon) hernias occur when direct and indirect hernias occur simultaneously.

D. Sliding hernias occur when part of the wall of the sac is formed by a viscera (bladder, colon). Richter's hernias occur when part of the bowel (rather than the entire circumference) becomes trapped. Only a "knuckle" of bowel enters the hernia sac.

E. Incarcerated hernias cannot be reduced into the abdominal cavity. Strangulated hernias are hernias with incarcerated contents and a compromised blood supply; intense pain indicates intestinal ischemia.

F. Inguinal anatomy

1. Layers of abdominal wall: Skin, subcutaneous fat, Scarpa's fascia, external oblique, internal oblique, transversus abdominis, transversalis fascia, peritoneum.

2. Hesselbach's triangle: A triangle formed by the lateral edge of the rectus sheath, the inferior epigastric vessels, and the inguinal ligament.

3. Inguinal ligament: Ligament running from the anterior superior iliac spine to the pubic tubercle.

4. Lacunar ligament: Reflection of inguinal ligament from the pubic tubercle onto the iliopectineal line of the pubic ramus.

5. Cooper's ligament: Strong, fibrous band located on the iliopectineal line of the superior pubic ramus.

6. External inguinal ring: Opening in the external oblique aponeurosis; the ring contains the ilioinguinal nerve and spermatic cord or round ligament.
58 Hernias

7. **Internal ring:** Bordered superiorly by the internal oblique muscle and inferomedially by the inferior epigastric vessels and the transversalis fascia.

8. **Processus vaginalis:** A diverticulum of peritoneum which descends with the testicle and lies adjacent to the spermatic cord. The processus vaginalis may enlarge to become the sac of an indirect inguinal hernia.

9. **Femoral canal:** Formed by the borders of the inguinal ligament, lacunar ligament, Cooper's ligament, and femoral sheath.

G. **Clinical evaluation**

1. **Inguinal hernias** usually present as an intermittent mass in the groin. The symptoms can usually be reproduced by a purposeful Valsalva maneuver. Abdominal obstruction may rarely be the first manifestation of a hernia.

2. **Physical examination.** An inguinal bulge with a smooth, rounded surface is usually palpable. The bulge may become larger with straining. The hernia sac can be assessed by inverting the hemiscrotum with an index finger passed through the external inguinal ring.

3. **Radiologic evaluation.** X-ray studies are not usually needed. Ultrasonography or CT scanning may be necessary to evaluate small hernias, particularly in the obese patient.

H. **Differential diagnosis.** Inguinal hernias are distinguished from femoral hernias by the fact that femoral hernias originate below the inguinal ligament. Inguinal adenopathy, lipomas, dilatation of the saphenous vein, and psoas abscesses may present as inguinal masses.

I. **Treatment**

1. **Preoperative evaluation and preparation.** Hernias should be treated surgically. If incarceration or strangulation has occurred, broad-spectrum antibiotics and nasogastric suction should be initiated.

2. **Reduction.** In uncomplicated cases, the hernia should be reduced by placing the patient in Trendelenburg’s position or by gentle pressure applied over the hernia. The hernia sac can be assessed by inverting the hemiscrotum with an index finger passed through the external inguinal ring.

3. **Surgical repair**

   a. **Indirect inguinal hernias.** The aponeurosis of the external oblique muscle should be opened, then the cremaster muscle is opened, and the contents of the cord identified. The hernia sac is separated from the cord structures and transected. The neck should then be ligated, and the posterior abdominal wall should be repaired.

   b. **Direct inguinal hernias.** The external oblique should be opened and the cord structures should be separated from the hernia sac, then the sac should be inverted. The posterior abdominal wall is repaired by approximating the inferior arch of the transversus muscle (conjoint tendon) to the iliohypogastric tract (Bassini repair).

   c. **Lichtenstein (Tension-Free) Repair.** A mesh plug or patch is often used to produce a “tension free” repair.

II. **Femoral hernias**

A. Femoral hernias account for 5% of all hernias, and 84% of femoral hernias occur in women. Incarceration or strangulation occur in 25% of femoral hernias.

B. In femoral hernias, the abdominal viscera and peritoneum protrude through the femoral ring into the upper thigh. The femoral ring is limited
medially by the lacunar ligament of Gimbernat, laterally by the femoral vein, anteriorly and proximally by the inguinal ligament, and posteriorly and distally by Cooper's ligament.

C. Clinical evaluation
1. Femoral hernias may present as a tender groin mass, and small-bowel obstruction may sometimes occur.

2. Physical examination. The hernia sac manifests clinically as a mass in the upper thigh, curving cranially over the inguinal region. It may appear while the patient is standing or straining and may disappear in the supine position.

D. Treatment. A Cooper's ligament repair (McVey) through the inguinal approach is recommended.

III. Abdominal wall hernias
A. Incisional hernias occur at sites of previous incisions. Hernias occur after 14% of abdominal operations.

B. Umbilical hernias are congenital defects. Most newborn umbilical hernias close spontaneously by the second year of life. Patients with ascites have a high incidence of umbilical hernias.

C. Epigastric hernias occur in the linea alba above the umbilicus.

D. Spigelian hernias protrude near the termination of the transversus abdominis muscle at the lateral edge of the rectus abdominis muscle.

E. Lumbar hernias occur superior to the iliac crest or below the last rib.

F. Obturator hernias pass through the obturator foramen and present with bowel obstruction and focal tenderness on rectal examination.

Inguinal Hernia Repair Technique

I. Indirect hernia
A. Prep and draped the skin of the abdomen, inguinal region, upper thigh, and external genitalia. Place the incision 1 cm above and parallel to the inguinal ligament. Begin the incision at a point just above, and medial to, the pubic tubercle, and extend it to a point two-thirds the distance to the anterior iliac spine. Incise the subcutaneous fat in the length of the incision down to the external oblique aponeurosis. Clear the external oblique muscle of overlying fat and identify the external inguinal ring. Incise the aponeurosis of the external oblique, beginning laterally and splitting the aponeurosis in the direction of its fibers, taking care not to injure the underlying ilioinguinal nerve. Expose the inguinal canal in which the spermatic cord and the indirect inguinal hernia are located.

B. Use blunt dissection to mobilize the spermatic cord and the associated hernia up to the level of the pubic tubercle. Lift these structures up from the floor of the inguinal canal, and encircle with a Penrose drain. Retract the drain anteriorly, and free the remainder of the cord from the floor of the canal. Use sharp and blunt dissection to incise the anterior muscular and fascial investments of the cord.

C. Sharply incise the internal spermatic fascia, and locate the hernial sac; identify the spermatic artery, venous plexus, and vas deferens before opening the sac.

D. Incise the indirect hernial sac anteriorly along its long axis. Place an index finger inside the hernial sac, and separate the sac from surrounding cord structures, using sharp and blunt dissection. Carry the dissection proximally to the internal inguinal ring.
60 Inguinal Hernia Repair Technique

E. Close the sac with a circumferential purse-string suture on an atraumatic, gastrointestinal needle. Tie this suture, being careful that no abdominal organs are within the purse string. Reinforce this ligation by placing another transfixion suture through the sac 1 mm distal to the purse-string suture. Transect the sac a few millimeters below the second suture, and cut both sutures and allow sac to retract into the retroperitoneum. Remove the sac. Inspect the floor of the inguinal canal. If there is only minimal dilation of the internal ring, the hernia repair can be completed by placing a few interrupted sutures at the medial border of the internal ring and completing a Bassini repair.

F. If the hernia is moderately sized, use a modification of the Bassini repair. Place a series of interrupted sutures in the transversalis fascia, beginning medially at the level of the pubic tubercle. Carry the sutures laterally as far as the medial border of the internal ring. Incorporate the posterior fibers of the conjoint tendon or use the posterior fascia of the transversalis abdominalus muscle with some of the muscular fibers of the internal oblique muscle.

G. Begin suturing medially at Cooper’s ligament, and transition at the femoral sheath to Poupart’s ligament. Place the sutures 1 cm apart, and use nonabsorbable monofilament 00 suture. Tie the sutures to reinforce the floor of the inguinal canal.

H. Replace the ilioinguinal nerve and the spermatic cord in the inguinal canal, and reapproximate the external oblique aponeurosis over the cord with interrupted, nonabsorbable, 000 sutures.

I. Close the subcutaneous tissues with interrupted, fine, absorbable sutures in Scarpa’s fascia, and close the skin with staples or subcuticular sutures. Apply a sterile dressing.

II. Repair of direct inguinal hernias

A. The skin incision is the same as for repair of the indirect inguinal hernia. The direct inguinal hernia appears as a diffuse bulge in the area of Hesselbach’s triangle, appreciated by palpating with a fingertip. Reduce the direct inguinal hernia with a series of interrupted, inverting, 00, nonabsorbable sutures placed in the redundant preperitoneal tissue.

B. The fascial defect in Hesselbach’s triangle is repaired with a Cooper’s ligament or modified McVay-type repair. Sharp and blunt dissection of the floor of the inferior portion of the inguinal canal should be used to expose the lacunar ligament and Cooper’s ligament. Dissect laterally along Cooper’s ligament as far as the medial aspect of the femoral vein. A relaxing incision should be made in the deep portion of the anterior rectus sheath, then grasp the medial and superior edge of the defect in Hesselbach’s triangle with Allis clamps.

C. A series of interrupted sutures is placed, beginning medially at the pubic tubercle, and carried laterally as far as the femoral vein. Check the appropriate snugness of the deep inguinal ring. When all sutures are placed, tie the sutures medial to lateral. Replace the cord and the ilioinguinal nerve in the bed of the inguinal canal, and reapproximate the external oblique aponeurosis over these structures.

III. Lichtenstein (Tension-Free) Repair

A. One of the most commonly performed open herniorrhaphy techniques is the tension-free (Lichtenstein) repair. A tension-free hernioplasty performed with mesh reinforcement of the inguinal floor significantly decreases the recurrence rate.

B. The Lichtenstein repair is routinely performed in an outpatient setting with
local anesthesia. A Marlex mesh patch is sutured to the aponeurotic tissue
overlying the pubic bone, with continuation of this suture along the edge
of the inguinal (Poupart’s) ligament to a point lateral to the internal inguinal
ring.
C. The lateral edge of the mesh is slit to allow passage of the spermatic
cord between the split limbs of the mesh. The cephalad edge of the mesh is
sutured to the conjoint tendon, with the internal oblique edge overlapped
by 2 cm. The two tails of the lateral aspect of the mesh are sutured
together, incorporating the margin of the inguinal ligament.
References: See page 108.

Upper Gastrointestinal Bleeding

I. Clinical evaluation
A. Initial evaluation of upper GI bleeding should estimate the duration of
hematemesis (vomiting bright red blood or coffee ground material) and
volume of bleeding. A history of bleeding occurring after forceful vomiting
suggests Mallory-Weiss Syndrome.
B. Abdominal pain, melena, hematochezia (bright red blood per rectum),
history of peptic ulcer, cirrhosis or prior bleeding episodes may be
present.
C. Precipitating factors. Use of aspirin, nonsteroidal anti-inflammatory
drugs, or anticoagulants should be sought.

II. Physical examination
A. General: Pallor and shallow rapid respirations may be present; tachy-
cardia indicates a 10% blood volume loss; postural hypotension, with an
increase in pulse of 20 and a decrease in systolic of 20, indicates a 20-
30% loss.
B. Skin: Delayed capillary refill and stigmata of liver disease (jaundice,
spider angiomas, parotid gland hypertrophy) should be sought.
C. Abdomen: Scars, tenderness, masses, hepatomegaly, and dilated
abdominal veins should be evaluated. Stool gross or occult blood should
be checked.

III. Laboratory evaluation: CBC, SMA 12, liver function tests, amylase,
INR/PTT, type and cross PRBC, FFP.

IV. Differential diagnosis of upper bleeding: Peptic ulcer, gastritis, esop-
hageal varices, Mallory-Weiss tear (gastroesophageal junction tear caused
by vomiting or retching), esophagitis, swallowed blood from epistaxis,
malignancy (esophageal, gastric), angiodysplasias, aorto-enteric fistula,
hematobilia.

V. Diagnostic approach to upper gastrointestinal bleeding
A. If the bleeding appears to have stopped or has significantly slowed,
medical therapy with H2 blockers and saline lavage is usually all that is
required.
B. A minimum of two 14-16 gauge IV lines should be placed. 1-2 liters of
normal saline solution should be infused until blood is ready, then trans-
sfuse 2-6 units of PRBCs as fast as possible. An estimate of blood
transfusion requirement should be based on the blood loss rate and vital
signs (typically 2-6 units PRBCs are needed).
C. A large bore nasogastric tube should be placed, followed by lavage with
2 L of room temperature tap water. The tube should then be connected
to low intermittent suction, and the lavage should be repeated hourly. The
Variceal bleeding

- NG tube may be removed when bleeding is no longer active.
- Oxygen is administered by nasal cannula, guided by pulse oximetry.
- Urine output should be monitored.
- Serial hematocrits should be checked and maintained greater than 30%.
- Coagulopathy should be assessed and corrected with fresh frozen plasma. A pulmonary artery catheter (Swan-Ganz) should be used to assess the effectiveness of resuscitation in unstable patients. Definitive diagnosis requires upper endoscopy, at which time electrocoagulation and/or local injection of vasoconstrictors at bleeding sites may be completed.

Mallory-Weiss syndrome

- This disorder is defined as a mucosal tear at the gastroesophageal junction following forceful retching and vomiting.
- Treatment is supportive, and the majority of patients stop bleeding spontaneously. Endoscopic coagulation or operative suturing may rarely be necessary.

Acute medical treatment of peptic ulcer disease

- Ranitidine (Zantac) 50 mg IV bolus, then continuous infusion at 6.25-12.5 mg/h [150-300 mg in 250 mL D5W over 24h (11 cc/h)], or 50 mg IV q6-8h OR
- Cimetidine (Tagamet) 300 mg IV bolus, then continuous infusion at 37.5-50 mg/h (900 mg in 250 mL D5W over 24h), or 300 mg IV q6-8h OR
- Famotidine (Pepcid) 20 mg IV q12h.

References: See page 108.

Variceal Bleeding

Hemorrhage from esophageal and gastric varices usually occurs as a complication of chronic liver disease.

Clinical evaluation

- Variceal bleeding should be considered in any patient who presents with significant upper gastrointestinal bleeding. Signs of cirrhosis may include spider angiomas, palmar erythema, leukonychia, clubbing, parotid enlargement, and Dupuytren's contracture. Jaundice, lower extremity edema and ascites are indicative of decompensated liver disease.
- The severity of the bleeding episode can be assessed on the basis of orthostatic changes (eg, resting tachycardia, postural hypotension), which indicate a one-third or more of blood volume loss.
- If the patient's sensorium is altered because of hepatic encephalopathy, the risk of aspiration mandates endotracheal intubation. Placement of a large-caliber nasogastric tube (22 F or 24 F) permits lavage for removal of blood and clots in preparation for endoscopy.
- Nasogastric lavage should be performed with tap water, because saline may contribute to retention of sodium and water.

Resuscitation

- Blood should be replaced as soon as possible. While blood for transfusion is being made available, intravenous volume should be replenished with intravenous albumin in isotonic saline solution (Albuminar-S) or normal saline solution if the patient does not have ascites or evidence of decompensation.
- Once euvoolemia is established, intravenous infusion should be changed
Variceal Bleeding

A. Pharmacologic agents
   1. Octreotide (Sandostatin) 50 mcg IV over 5-10 min, followed by 50 mcg/h for 48 hours (1200 mcg in 250 mL D5W); somatostatin analog; beneficial in controlling hemorrhage.
   2. Vasopressin (Pitressin), a posterior pituitary hormone, causes splanchnic arteriolar vasoconstriction and reduction in portal pressure.
      a. Dosage is 20 units IV over 20-30 min, then 0.2-0.4 units/minute (100 U in 250 mL D5W).
      b. Concomitant use of IV nitroglycerin paste (1 inch q6h) mitigates the vasoconstrictor effects of vasopressin on the myocardial and splanchnic circulations.
   3. Octreotide or vasopressin should be tapered and discontinued over a 24-hour period once hemorrhage has subsided.

B. Tamponade devices
   1. Bleeding from varices may temporarily be reduced with tamponade balloon tubes. However, the benefit is temporary, and prolonged tamponade causes severe esophageal ulceration and has a high rebleeding rate.
   2. The Linton-Nachlas tube is recommended. It has a gastric balloon and several ports in the esophageal component. The tube is kept in place for 6 to 12 hours while preparations for endoscopic or radiologic treatment are being made.

C. Endoscopic management of bleeding varices
   1. Endoscopic sclerotherapy involves injection of a sclerosant into varices. The success of the treatment is enhanced by a second sclerotherapy treatment.
   2. Endoscopic variceal ligation involves placement of tiny rubber bands on varices during endoscopy. Ligation is associated with fewer complications than sclerotherapy, but both have comparable efficacy.

D. Surgery
   1. Portal-systemic shunt surgery is the most definitive therapy for bleeding varices. The placement of a shunt creates an anastomosis between portal and systemic veins, allowing decompression of the hypertensive portal venous system, preventing rebleeding. However, the procedures have a 30-40% rate of hepatic encephalopathy, and there is only a slight survival advantage over medical treatment.
   2. Shunts that preserve portal blood flow are preferred, such as the distal splenorenal and the small-diameter portacaval H-graft shunts.

E. Transjugular intrahepatic portacaval shunt (TIPS)
   1. Under fluoroscopy, a needle is advanced into the liver through the internal jugular and hepatic veins, and inserted into a large branch of the portal vein. A balloon is then used to enlarge the track to permit the placement of a stent.
   2. Encephalopathy occurs in about 35% of patients and there is a significant risk of shunt thrombosis or stenosis.
IV. Approach to treatment of variceal hemorrhage
A. Patients initially should be given an octreotide (Sandostatin) or vasopressin infusion plus nitroglycerin while awaiting endoscopic treatment.
B. If varices are large, endoscopic ligation is preferred. If there is active bleeding from a spurting varix, sclerotherapy is best.
C. Failure of endoscopic therapy warrants the use of a portal-systemic shunt. Liver transplantation should be considered in poor-risk patients and when other therapies fail.

References: See page 108.

Peptic Ulcer Disease

Peptic ulcer disease is diagnosed in 500,000 patients each year. Patients with peptic ulcer disease should be treated as having an infectious illness caused by the bacterium Helicobacter pylori. Peptic ulcer disease due to H pylori infection can be cured with a combination of antimicrobial and antisecretory drugs.

I. Pathophysiology
A. Helicobacter pylori (HP), a spiral-shaped, flagellated organism, is the most frequent cause of peptic ulcer disease (PUD). Nonsteroidal anti-inflammatory drugs (NSAIDs) and pathologically high acid-secreting states (Zollinger-Ellison syndrome) are less common causes. More than 90% of ulcers are associated with H. pylori. Eradication of the organism cures and prevents relapses of gastroduodenal ulcers.
B. Complications of peptic ulcer disease include bleeding, duodenal or gastric perforation, and gastric outlet obstruction (due to inflammation or strictures).

II. Clinical evaluation
A. Symptoms of PUD include recurrent upper abdominal pain and discomfort. The pain of duodenal ulceration is often relieved by food and antacids and worsened when the stomach is empty (eg, at nighttime). In gastric ulceration, the pain may be exacerbated by eating.
B. Nausea and vomiting are common in PUD. Hematemesis (“coffee ground” emesis) or melena (black tarry stools) are indicative of bleeding.
C. Physical examination. Tenderness to deep palpation is often present in the epigastrium, and the stool is often guaiac-positive.

<table>

<tr>
<td>Occurs with hunger or hours after meals</td>
</tr>
<tr>
<td>Usually temporarily relieved by meals or antacids</td>
</tr>
<tr>
<td>Persistence or recurrence over months to years</td>
</tr>
<tr>
<td>History of self-medication and intermittent relief</td>
</tr>
</tbody>
</table>

D. NSAID-related gastrointestinal complications. NSAID use and H pylori infection are independent risk factors for peptic ulcer disease. The risk is 5 to 20 times higher in persons who use NSAIDs than in the general population. Misoprostol (Cytotec) has been shown to prevent
Peptic Ulcer Disease

both NSAID ulcers and related complications. The minimum effective dosage is 200 micrograms twice daily; total daily doses of 600 micrograms or 800 micrograms are significantly more effective.

III. Laboratory and diagnostic testing

A. Alarm signs and symptoms that suggest gastric cancer are indications for early endoscopy or upper gastrointestinal radiology studies.

<table>
<thead>
<tr>

<td>Vomiting (severe)</td>
</tr>
<tr>
<td>New-onset symptoms in persons $\leq 45$ yr of age</td>
<td></td>
</tr>
</tbody>
</table>

B. Noninvasive testing for H pylori

1. In the absence of alarm symptoms for gastric cancer, most patients with dyspepsia should undergo evaluation for H pylori infection with serologic testing for H pylori antigens.

2. Serologic testing to detect H pylori antibodies is the preferred testing method. Serologic testing is highly sensitive, but it cannot be used for follow-up after therapy because antibody titers may remain elevated for a year or longer. Rapid office-based serologic kits have a sensitivity of 90% and a specificity of 85%.

3. Urea breath tests measure the carbon dioxide produced when H pylori urease metabolizes urea labeled with radioactive carbon (13C or 14C). The 13C test does not involve a radioactive isotope and, unlike the 14C test, can be used in children and pregnant women. With the 13C test, exhaled breath samples are usually sent to a central testing facility. The 14C test, which exposes the patient to a small dose of radiation, can be analyzed in a hospital's nuclear medicine laboratory. Urea breath tests have a sensitivity and specificity of 90-99%. The urea breath test is the best method of confirmation of care.

4. Stool testing for H pylori antigens has an accuracy for pretreatment testing of H pylori that is similar to that of other available tests.

5. Biopsy-based testing performed at endoscopy can provide valuable information via histologic testing, rapid urease tests, and culture. Sensitivity of the tests for H pylori ranges from 80% to 100%, and specificity exceeds 95%.

IV. Treatment of peptic ulcer disease

A. Combination therapy

1. Dual therapy is not recommended because cure rates for all regimens are less than 85%. Recommended triple therapies consist of a bismuth preparation or proton pump inhibitor or H2 receptor antagonist plus two antibiotics.
## Triple Therapies for Peptic Ulcer Disease

### BMT Therapy:
- Bismuth subsalicylate (Pepto-Bismol), 2 tablets with meals and at bedtime for 14 days and
- Metronidazole (Flagyl), 250 mg with meals and at bedtime (total daily dose, 1,000 mg) for 14 days and
- Tetracycline, 500 mg with meals and at bedtime (total daily dose, 2 g) for 14 days or
- A prepackaged triple-therapy agent (Helidac), to be taken qid for 14 days, consists of 525 mg bismuth subsalicylate, 250 mg metronidazole, and 500 mg tetracycline; an H2-blocker or proton pump inhibitor should be added (Omeprazole [Prilosec], 20 mg gid or lansoprazole [Prevacid], 15 mg qid).

### Ranitidine Bismuth Citrate (Tritec), 1 tablet (400 mg) bid for 14 days and
- Tetracycline, 500 mg bid for 14 days and
- Clarithromycin (Biaxin) or metronidazole (Flagyl), 500 mg bid for 14 days

### Omeprazole (Prilosec), 20 mg bid, or lansoprazole (Prevacid), 30 mg bid and
- Clarithromycin (Biaxin), 250 or 500 mg bid for 14 days and
- Metronidazole (Flagyl), 500 mg bid, or amoxicillin, 1 g bid for 14 days or
- A prepackaged triple-therapy agent (Prevac), to be taken bid for 14 days, consists of 30 mg lansoprazole, 1 g amoxicillin, and 500 mg clarithromycin.

---

2. The *H pylori* eradication rate is 96% for patients who take more than 60% of their medication.

### B. Confirmation of Cure of *H pylori* Infection

1. Confirmation of cure of *H pylori* infection is always necessary. About 75% of patients presumed to have uncomplicated peptic ulcer disease due to *H pylori* infection are cured after one course of therapy.

2. The urea breath test is the best method for assessing the effectiveness of therapy. The stool antigen test is only slightly less accurate, and its use should be considered when breath testing is not available.

3. Confirmation of cure must be delayed until at least 4 to 6 weeks after completion of antimicrobial therapy. Treatment with proton pump inhibitors must be discontinued at least 1 week before urea breath testing to confirm cure. H2-receptor antagonists have no effect on the urea breath test and need not be discontinued before confirmation testing.

### C. Treatment of NSAID-Related Ulcers

1. When the ulcer is caused by NSAID use, healing of the ulcer is greatly facilitated by discontinuing the NSAID. Acid antisecretory therapy with an H2-blocker or proton pump inhibitor speeds ulcer healing. Proton pump inhibitors are more effective in inhibiting gastric acid production and are often used to heal ulcers in patients who require continuing NSAID treatment.

2. If serologic or endoscopic testing for *H pylori* is positive, antibiotic treatment is necessary.
Lower Gastrointestinal Bleeding

3. Acute H₂-blocker therapy
   a. Ranitidine (Zantac), 150 mg bid or 300 mg qhs.
   b. Famotidine (Pepcid), 20 mg bid or 40 mg qhs.
   c. Nizatidine (Axid Pulvules), 150 mg bid or 300 mg qhs.
   d. Cimetidine (Tagamet). 400 mg bid or 800 mg qhs.

4. Proton pump inhibitors
   a. Omeprazole (Prilosec), 20 mg qd.
   b. Lansoprazole (Prevacid), 15 mg before breakfast qd.

V. Surgical treatment of peptic ulcer disease
   A. Indications for surgery include exsanguinating hemorrhage, >5 units transfusion in 24 hours, rebleeding during same hospitalization, intractability, perforation, gastric outlet obstruction, and endoscopic signs of rebleeding.
   B. Unstable patients should receive a truncal vagotomy, oversewing of bleeding ulcer bed, and pyloroplasty.

References: See page 108.

Lower Gastrointestinal Bleeding

S.E. Wilson, MD

The spontaneous remission rate for lower gastrointestinal bleeding, even with massive bleeding, is 80%. No source of bleeding can be identified in 12%, and bleeding is recurrent in 25%. Bleeding has usually ceased by the time the patient presents to the emergency room.

I. Clinical evaluation
   A. The severity of blood loss and hemodynamic status should be assessed immediately. Initial management consists of resuscitation with crystalloid solutions (lactated Ringers solution) and blood products if necessary.
   B. The duration and quantity of bleeding should be assessed; however, the duration of bleeding is often underestimated.
   C. Risk factors that may have contributed to the bleeding include nonsteroidal anti-inflammatory drugs, anticoagulants, colonic diverticulosis, renal failure, coagulopathy, colonic polyps and hemorrhoids. Patients may have a history of hemorrhoids, diverticulosis, inflammatory bowel disease, peptic ulcer, gastritis, cirrhosis, or esophageal varices.
   D. Hematochezia. Bright red or maroon blood per rectum suggests a lower GI source; however, 11-20% of patients with an upper GI bleed will have hematochezia as a result of rapid blood loss.
   E. Melena. Sticky, black, foul-smelling stools suggest a source proximal to the ligament of Treitz, but melena can also result from bleeding in the small intestine or proximal colon.
   F. Change in stool caliber, anorexia, weight loss and malaise are suggestive of malignancy.
   G. Associated findings
      1. Abdominal pain may result from ischemic bowel, inflammatory bowel disease, or a ruptured aortic aneurysm.
      2. Painless, massive bleeding suggests vascular bleeding from diverticula, angiodysplasia or hemorrhoids.
      3. Bloody diarrhea suggests inflammatory bowel disease or an
68 Lower Gastrointestinal Bleeding

4. **Bleeding with rectal pain** is seen with anal fissures, hemorrhoids, and rectal ulcers.
5. **Chronic constipation** suggests hemorrhoidal bleeding. New onset constipation or thin stools suggests a left-sided colonic malignancy.
6. **Blood on the toilet paper or dripping** into the toilet water after a bowel movement suggests a perianal source.
7. **Blood coating the outside of stool** suggests a lesion in the anal canal.
8. **Blood streaking or mixed in with the stool** may result from a polyp or malignancy in the descending colon.
9. **Maroon colored stools** often indicates small bowel and proximal colon bleeding.

II. Physical examination
A. Postural hypotension indicates a 20% blood volume loss; whereas, overt signs of shock (pallor, hypotension, tachycardia) indicate a 30-40% blood loss.
B. The skin may be cool and pale with delayed capillary refill if bleeding has been significant.
C. Stigmata of liver disease, including jaundice, caput medusae, gynecomastia and palmar erythema, should be sought because these patients frequently have GI bleeding.

III. Differential diagnosis of lower gastrointestinal bleeding
A. Angiodysplasia and diverticular disease of the right colon account for the vast majority of episodes of acute lower gastrointestinal bleeding. Most acute LGI bleeding originates from the colon; however, 15-20% of episodes arise from the small intestine and the upper gastrointestinal tract.
B. Elderly patients. Diverticulosis and angiodysplasia are the most common causes of lower GI bleeding.
C. Younger patients. Hemorrhoids, anal fissures, and inflammatory bowel disease are more common causes.

IV. Diagnosis and management of lower gastrointestinal bleeding
A. Rapid clinical evaluation and resuscitation should precede diagnostic or therapeutic studies. Intravenous fluids (1-2 liters) should be infused over 10-20 minutes to restore intravascular volume, and blood should be transfused if there is rapid ongoing blood loss or if hypotension or tachycardia is present. Coagulopathy is corrected with fresh frozen plasma or platelets.
B. When small amounts of bright red blood are passed per rectum, the lower gastrointestinal tract can be assumed to be the source.
C. In patients with large-volume maroon stools, nasogastric tube aspiration should be performed to exclude massive upper gastrointestinal hemorrhage.
D. If the nasogastric aspirate contains no blood, then anoscopy and sigmoidoscopy should be performed to determine whether a colonic mucosal abnormality (ischemic or infectious colitis) or hemorrhoids might be the cause of bleeding.
E. Colonoscopy in a patient with massive lower GI bleeding is often nondiagnostic, but it can detect ulcerative colitis, antibiotic associated colitis, and ischemic colon.
F. Polyethylene glycol-electrolyte solution (CoLyte or GoLYTELY) should be administered orally or by means of a nasogastric tube. Four liters of...
solution is given over a 2- to 3-hour period. This allows for diagnostic and therapeutic colonoscopy and adequately prepares the bowel should emergency operation become necessary.

V. Definitive management of lower gastrointestinal bleeding

A. Colonoscopy

1. Colonoscopy is the procedure of choice for diagnosing colonic causes of gastrointestinal bleeding. It should be performed after adequate preparation of the bowel. If the bowel cannot be adequately prepared because of persistent, acute bleeding, a bleeding scan or angiography is preferable.

2. Endoscopy may be therapeutic for angiodysplastic lesions, or polyps, which can be coagulated.

3. If colonoscopy fails to reveal a source for the bleeding, the patient should be observed because, in about 80% of cases, bleeding ceases spontaneously.

B. Bleeding scan. The technetium-labeled (“tagged”) red blood cell bleeding scan can detect bleeding sites when bleeding is intermittent. Localization may not be precise enough to allow segmental colon resection.

C. Angiography

1. Selective visceral angiography detects arterial bleeding that occurs at a rate of 0.5 mL/min or faster. Diverticular bleeding causes pooling of contrast medium within a diverticulum.

2. Bleeding angiodysplastic lesions appear as abnormal vasculature. When active bleeding is seen with diverticular disease or angiodysplasia, selective arterial infusion of vasopressin may be effective.

D. Surgery

1. If bleeding continues and no source has been found, surgical intervention is warranted.

2. Surgical resection may be indicated for patients with recurrent diverticular bleeding, or for patients who have had persistent bleeding from colonic angiodysplasia and have required blood transfusions. Treatment of lower gastrointestinal bleeding involves resection of the involved segment.

VI. Angiodysplasia

A. Angiodysplastic lesions are small vascular tufts that are formed by capillaries, veins, and venules, appearing as red dots or 2 to 10 mm spider-like lesions.

B. Angiodysplastic lesions develop secondary to chronic colonic distention, and they have a prevalence of 25% in elderly patients.

C. The most common site of bleeding is the right colon. Most patients with angiodysplasia have recurrent minor bleeding; however, massive bleeding may occur.

VII. Diverticular disease

A. Diverticular disease is the most common cause of acute lower gastrointestinal bleeding. Sixty to 80% of bleeding diverticula are located in the right colon. Ninety percent of all diverticula are found in the left colon.

B. Diverticular bleeding tends to be massive, but it stops spontaneously in 80% of patients. The rate of rebleeding is 25%.

VIII. Colon polyps and colon cancers

A. Colon polyps and colon cancers rarely cause significant acute LGI hemorrhage. Left-sided and rectal neoplasms are more likely to cause
Anorectal Disorders

I. Hemorrhoids
    A. Hemorrhoids are dilated veins located beneath the lining of the anal canal. Internal hemorrhoids are located in the upper anal canal. External hemorrhoids are located in the lower anal canal.
    B. The most common symptom of internal hemorrhoids is painless rectal bleeding, which is usually bright red and ranges from a few drops to a spattering stream at the end of defecation. If internal hemorrhoids remain prolapsed, a dull aching may occur. Blood and mucus stains may appear on underwear, and itching in the perianal region is common.

    | Classification of Internal Hemorrhoids |
    |-----------------|---------------------|
    | Grade | Description | Symptoms |
    |-------|-------------|----------|
    | 1     | Non-prolapsing | Minimal bleeding |
    | 2     | Prolapse with straining, reduce when spontaneously prolapsed | Bleeding, discomfort, pruritus |
    | 3     | Prolapse with straining, manual reduction required when prolapsed | Bleeding, discomfort, pruritus |

References: See page 108.

C. Management of internal hemorrhoids
1. Grade 1 and uncomplicated grade 2 hemorrhoids are treated with dietary modification (increased fiber and fluids).
2. Symptomatic grade 2 and grade 3 hemorrhoids. Treatment consists of hemorrhoid banding with an anoscope. Major complications are rare and consist of excessive pain, bleeding, and infection. Surgical hemorrhoidectomy may sometimes be necessary.
3. Grade 4 hemorrhoids require surgical hemorrhoidectomy.
D. External hemorrhoids
1. External hemorrhoids occur most often in young and middle-aged adults, becoming symptomatic only when they become thrombosed.
2. External hemorrhoids are characterized by rapid onset of constant burning or throbbing pain, accompanying a new rectal lump. Bluish skin-covered lumps are visible at the anal verge.
3. Management of external hemorrhoids
   a. If patients are seen in the first 48 hours, the entire lesion can be excised in the office. Local anesthetic is infiltrated, and the thrombus and overlying skin are excised with scissors. The resulting wound heals by secondary intention.
   b. If thrombosis occurred more than 48 hours prior, spontaneous resolution should be permitted to occur.

II. Anal fissures
A. An anal fissure is a longitudinal tear in the distal anal canal, usually in the posterior or anterior midline. Patients with anal fissures complain of perirectal pain which is sharp, searing or burning and is associated with defecation. Bleeding from anal fissures is bright red and not mixed with the stool.
B. Anal fissures may be associated with secondary changes such as a sentinel tag, hypertrophied anal papilla, induration of the edge of the fissure, and anal stenosis. Crohn’s disease should be considered if the patient has multiple fissures, or whose fissure is not in the midline.
C. Anal fissures are caused by spasm of the internal anal sphincter. Risk factors include a low-fiber diet and previous anal surgery.
D. Treatment of anal fissures
1. High-fiber foods, warm sitz baths, stool softeners (if necessary), and daily application of 1% hydrocortisone cream to the fissure should be initiated. These simple measures may heal acute anal fissures within 3 weeks in 90% of patients.
2. Lateral partial internal sphincterotomy is indicated when 4 weeks of medical therapy fails. The procedure consists of surgical division of a portion of the internal sphincter, and it is highly effective. Adverse effects include incontinence to flatus and stool.

III. Levator ani syndrome and proctalgia fugax
A. Levator ani syndrome refers to chronic or recurrent rectal pain, with episodes lasting 20 minutes or longer. Proctalgia fugax is characterized by anal or rectal pain, lasting for seconds to minutes and then disappearing for days to months.
B. Levator ani syndrome and proctalgia fugax are more common in patients
72 Anorectal Disorders

under age 45, and psychological factors are not always present.

C. Levator ani syndrome is caused by chronic tension of the levator muscle. Proctalgia fugax is caused by rectal muscle spasm. Stressful events may trigger attacks of proctalgia fugax and levator ani syndrome.

D. Diagnosis and clinical features
1. Levator ani syndrome is characterized by vague, indefinite rectal discomfort or pain. The pain is felt high in the rectum and is sometimes associated with a sensation of pressure.
2. Proctalgia fugax causes pain that is brief and self-limited. Patients with proctalgia fugax complain of sudden onset of intense, sharp, stabbing or cramping pain in the anorectum.
3. In patients with levator ani syndrome, palpation of the levator muscle during digital rectal examination usually reproduces the pain.

E. Treatment
1. Levator ani syndrome. Treatment with hot baths, nonsteroidal anti-inflammatory drugs, muscle relaxants, or levator muscle massage is recommended. EMG-based biofeedback may provide improvement in pain.
2. Proctalgia fugax. For patients with frequent attacks, physical modalities such as hot packs or direct anal pressure with a finger or closed fist may alleviate the pain. Diltiazem and clonidine may provide relief.

IV. Pruritus ani
A. Pruritus ani is characterized by the intense desire to scratch the skin around the anal orifice. It occurs in 1% of the population. Pruritus ani may be related to fecal leakage.
B. Patients report an escalating pattern of itching and scratching in the perianal region. These symptoms may be worse at night. Anal hygiene and dietary habits, fecal soiling, and associated medical conditions should be sought.
C. Examination reveals perianal maceration, erythema, excoriation, and lichenification. A digital rectal examination and anoscopy should be performed to assess sphincter tone and look for secondary causes of pruritus. Patients who fail to respond to 3 or 4 weeks of conservative treatment should undergo further investigations such as skin biopsy and sigmoidoscopy or colonoscopy.

D. Treatment and patient education
1. Patients should clean the perianal area with water following defecation, but avoid soaps and vigorous rubbing. Following this, the patient should dry the anus with a hair dryer or by patting gently with cotton. Between bowel movements a thin cotton pledget dusted with unscented cornstarch should be placed against the anus. A high fiber diet is recommended to regulate bowel movements and absorb excess liquid. All foods and beverages that exacerbate the itching should be eliminated.
2. Topical medications are not recommended because they may cause further irritation. If used, a bland cream such as zinc oxide or 1% hydrocortisone cream should be applied sparingly two to three times a day.
3. Diphenhydramine (Benadryl) or hydroxyzine (Vistaril) may relieve the itching and allow the patient to sleep.

V. Perianal abscess
A. The anal glands, located in the base of the anal crypts at the level of the
dentate line, are the most common source of perianal infection. Acute infection causes an abscess, and chronic infection results in a fistula.

B. The most common symptoms of perianal abscess are swelling and pain. Fevers and chills may occur. Perianal abscess is common in diabetic and immunosuppressed patients, and there is often a history of chronic constipation. A tender mass with fluctuant characteristics or induration is apparent on rectal exam.

C. Management of perianal abscess. Perianal abscesses are treated with incision and drainage using a local anesthetic. Large abscesses require regional or general anesthesia. A cruciate incision is made close to the anal verge and the corners are excised to create an elliptical opening which promotes drainage. An antibiotic, such as Zosyn, Timentin, or Cefotetan, is administered.

D. About half of patients with anorectal abscesses will develop a fistula tract between the anal glands and the perianal mucosa, known as a fistula-in-ano. This complication manifests as either incomplete healing of the drainage site or recurrence. Healing of a fistula-in-ano requires a surgical fistulotomy.

### Fistula-in-ano

A fistula-in-ano develops when an anorectal abscess forms a fistula between the anal canal and the perianal skin. The fistula may develop after an anorectal abscess has been drained operatively, or the fistula may develop spontaneously.

I. Clinical evaluation

A. The fistula is characterized by persistent purulent or feculent drainage, soiling the underwear.

B. The fistula orifice can be seen just outside the anal verge. Complex fistulae may have multiple tracts with multiple orifices.

II. Treatment of fistula-in-ano

A. Fistulae will not resolve without definitive treatment. The more common type of fistula, located at the anorectal junction, has an external opening where it can be drained operatively. The entire epithelialized tract must be found and obliterated.

B. Goodall's rule predicts the course of fistulae that exit the skin within 3 cm of the anal verge. Anterior fistulae go straight toward the anorectal junction; posterior fistulae curve toward the posterior midline and enter the anorectal junction.

C. A pilonidal cyst-sinus (coccygeal region) can be difficult to distinguish from a fistula-in-ano. Probing the tract under anesthesia usually will reveal its origin.

D. Fistulotomy. For fistulae that do not cross both internal and external sphincters, the tract should be unroofed and curetted. The lesion should then be allowed to heal by secondary intention.

E. Fistulectomy. Deeper fistulae should be treated by coring out the epithelialized tract to its origin. The fistula may recur.

F. Seton procedure. Complex fistulae or fistulae that traverse the sphincter can be treated by looping a heavy suture through the entire tract under tension. The suture should be tightened weekly until it “cuts” gradually to the surface. The tract will heal gradually behind the suture.
Colorectal Cancer

Charles Theuer, MD

Colorectal cancer is the second most common solid malignancy in adults and the second leading cause of cancer death in the US.

I. Clinical evaluation of colorectal cancer
   A. Flexible sigmoidoscopy is indicated for screening of asymptomatic, healthy adults over age 50. All adults with anemia or guaiac positive stools should be evaluated for colorectal cancer; older adults (>40) should be evaluated even if other sources of bleeding have been found. Hemorrhoids and cancer can coexist.
   B. Flexible sigmoidoscopy plus air contrast barium enema is adequate to evaluate the colon when the source of bleeding is thought to be benign anorectal disease. Total colonoscopy should be performed for any adult with gross or occult rectal bleeding and no apparent anorectal source.
   C. Left-sided or rectal lesions are characterized by blood streaked stools, change in caliber or consistency of stools, obstipation, alternating diarrhea and constipation, and tenesmus.
   D. Right-sided lesions are characterized by a triad of iron deficiency anemia, right lower quadrant mass, and weakness. Cancers occasionally present as a large bowel obstruction, perforation or abscess.

II. Laboratory evaluation
   A. Complete blood count with indices will often reveal a hypochromic, microcytic anemia. Liver function tests may sometimes be elevated in metastatic disease.
   B. Carcinoembryonic antigen (CEA) may be elevated in colorectal cancer, but it is a nonspecific test which may also be elevated in other malignancies, inflammatory bowel disease, cigarette smokers, and some normal persons. CEA is valuable in monitoring the response to treatment and as a marker for recurrence of metastases, requiring adjuvant therapy. It should be measured prior to resection of the tumor and at intervals postoperatively.
   C. Colorectal cancer is detected by colonoscopy with biopsies. Barium enema may complement colonoscopy since BE shows the exact anatomic location of the tumor. A chest X-ray should be done to search for metastases to the lungs. A CT scan should be done in cases where liver function test are elevated.

III. Management of colorectal carcinoma
   A. Surgical resection is indicated for colorectal adenocarcinoma, regardless of stage. Resection of the primary lesion prevents obstruction or perforation.
   B. Extremely advanced rectal lesions, which are not resectable, may be candidates for palliative radiation and a diverting colostomy.
   C. The extent of resection is determined by the relationship of the lesion to the lymphatic drainage and blood supply of the colon.
   1. Cecum or right colon. Right hemicolecctomy.
   2. Hepatic flexure. Extended right hemicolecctomy.
   3. Mid-transverse colon: Transverse colectomy or extended left or right hemicolecctomy.
4. Splenic flexure or left colon. Left hemicolectomy.
5. Sigmoid colon. Sigmoid colectomy.
6. Upper or middle rectum. Low anterior rectosigmoid resection with primary anastomosis.
7. Lower rectum. Abdominoperineal resection with permanent, end-colostomy or local excision.

D. Preoperative bowel preparation
1. Mechanical cleansing of the lumen, followed by decontamination with nonabsorbable oral antibiotics decreases the chance of infectious complications and allows for primary anastomosis. Fully obstructed patients cannot be prepped and must have a temporary colostomy.
2. Polyethylene glycol solution (CoLyte or GoLYTELY) is usually administered as 4 liters over 4 hours on the day before surgery. Oral phospho-soda (given as two 1½ ounce doses in 8 ounces of water) can be substituted for polyethylene glycol in patients with normal renal function. The Nichols-Condon prep consists of 1 g neomycin sulfate and 1 g erythromycin base PO at 2:00, 3:00 and 11:00 pm the day before operation. Cefotetan is given 1-2 gm IV 30 minutes before operation.
3. Patients with middle and lower rectal tumors should be staged with endoanal ultrasound. Tumors that invade through the muscularis propria (T3) or involve lymph nodes (N1) should be offered neoadjuvant therapy with radiation therapy and 5-fluorouracil.

E. Adjuvant chemotherapy is recommended for advanced colon lesions with the addition of pelvic radiation for advanced rectal tumors. Adjuvant therapy is reserved for locally advanced lesions (B2) or those with metastases to regional lymph nodes or distant organs (C1, C2, D).

F. Pathologic staging of the tumor is done postoperatively by histologic examination of the surgical specimen.

IV. Staging of colorectal carcinoma
A. Astler-Coller modification of Dukes’ Classification
Stage A: Limited to mucosa and submucosa. Nodes negative.
Stage B1: Extends into, but not through, muscularis propria; nodes negative.
Stage B2: Extends through muscularis propria; nodes negative.
Stage C1: Same as B1, except nodes positive.
Stage C2: Same as B2, except nodes positive.

V. Management of obstructing carcinomas of the left colon
A. Correct fluid deficits and electrolyte abnormalities. Nasogastric suction is useful, but it is not adequate to decompress the acutely obstructed colon.
B. The Hartmann procedure is indicated for distal descending and sigmoid colon lesions. This procedure consists of resection of the obstructing cancer and formation of an end-colostomy and blind rectal pouch. The colostomy can be taken down and anastomosed to the rectal pouch at a later date.
C. Primary resection with temporary end-colostomy and mucous fistula should be done for lesions of the transverse and proximal descending colon. This procedure consists of resection of the obstructing cancer and creation of a functioning end-colostomy and a defunctionalized distal limb with separate stomas. The colostomy can be taken down and continuity restored at a later date.
D. An emergency decompressive loop colostomy can be considered for acutely ill patients. After four to six weeks, a hemicolectomy can be
76 Mesenteric Ischemia

completed. A primary anastomosis may be done in selected patients with a prepared bowel.

VI. Management of obstructing carcinomas of the ascending colon. Correct fluid deficits, electrolyte abnormalities, and initiate nasogastric suction. A right hemicolectomy with primary anastomosis of the terminal ileum to the transverse colon can be performed on most patients. A temporary ileostomy is rarely needed.

References: See page 108.

Mesenteric Ischemia

Mesenteric ischemia is classified as acute mesenteric ischemia (AMI) and chronic mesenteric ischemia (CMI). AMI is subdivided into occlusive and nonocclusive mesenteric ischemia. Occlusive mesenteric ischemia results from either thrombotic or embolic arterial or venous occlusion. Approximately 80% of cases of AMI are occlusive in etiology, with arterial emboli or thromboses in 65% of cases and venous thrombosis in 15%. Arterial occlusions result from emboli in 75% of patients and in situ thrombosis cause the remaining 25%. Nonocclusive mesenteric ischemia is caused by low perfusion states and is responsible for 20% of AMI.

I. Clinical evaluation

A. Mesenteric arterial embolism

1. The median age of patients presenting with mesenteric arterial embolism is 70 years. The overwhelming majority of emboli lodge in the superior mesenteric artery (SMA). Emboli originating in the left atrium or ventricle are the most common cause of SMA embolism.

2. Risk factors include advanced age, coronary artery disease, cardiac valvular disease, history of dysrhythmias, atrial fibrillation, post-myocardial infarction mural thrombi, history of thromboembolic events, aortic surgery, aortography, coronary angiography, and aortic dissection. A previous history of peripheral emboli is present in 20%.

3. The disorder usually presents as sudden onset of severe poorly localized periumbilical pain, associated with nausea, vomiting, and frequent bowel movements. Pain is usually out of proportion to the physical findings and may be the only presenting symptom.

4. The abdomen may be soft with only mild tenderness. Absent bowel sounds, abdominal distension or guarding are indicative of severe disease.

5. Blood in the rectum is present in 16% of patients, and occult blood is present in 25% of patients. Peritoneal signs develop when the ischemic process becomes transmural.

B. Mesenteric arterial thrombosis

1. Thrombosis usually occurs in the area of atherosclerotic narrowing in the proximal SMA. The proximal jejunum through the distal transverse colon becomes ischemic.

2. SMA thrombosis usually occurs in patients with chronic, severe, visceral atherosclerosis. A history of abdominal pain after meals is present in 20-50% of patients. Patients are often elderly, with coronary artery disease, severe peripheral vascular disease, or hypertension.

3. SMA thrombosis presents with gradual onset of abdominal pain and distension. A history of postprandial abdominal pain and weight loss is
present in half of cases. Pain is usually out of proportion to the physical findings, and nausea and vomiting are common.

4. Signs of peripheral vascular disease, such as carotid, femoral or abdominal bruises, or decreased peripheral pulses are frequent. Abdominal distension, absent bowel sounds, guarding, rebound and localized tenderness, and rigidity indicate advanced bowel necrosis.

II. Diagnostic evaluation of acute mesenteric ischemia

A. Leukocyte count is elevated in most cases of mesenteric ischemia. In patients with SMA emboli, 42% have a metabolic acidosis. The serum amylase is elevated in half of patients.

B. Plain radiography. Abdominal and chest x-rays help to exclude the presence of free air or bowel obstruction. In rare instances, plain films of the abdomen reveal signs of ischemic bowel such as pneumatosis intestinalis, portal venous gas, or a thickened bowel wall with thumbprinting. However, plain films will be normal in the majority of cases.

C. Angiography is the gold standard for the diagnosis of AMI and is also used for therapeutic infusion of the vasodilator, papaverine. After obtaining plain abdominal films to rule out the presence of free air or obstruction, angiography must be obtained, especially in those patients in whom there is a strong clinical suspicion for AMI.

III. Emergency management

A. Stabilization and initial management

1. Patients with significant hypotension require rapid fluid resuscitation, and vasopressors may be used.

2. If hemoglobin is low, blood should be given. Patients who appear acutely ill should receive parenteral antibiotics to cover for gram-negative enteric bacteria as well as anaerobes after blood cultures are drawn.

B. Papaverine

1. Intraarterial infusion of papaverine into the superior mesenteric artery will increase mesenteric perfusion by relieving mesenteric vasoconstriction.

2. Papaverine is started at angiography and continued postoperatively if laparotomy is performed. The dosing is 60 mg IV bolus, followed by a 30-60 mg/h continuous infusion at a concentration of 1 mg/mL. Papaverine improves survival by 20-50%.

C. Acute mesenteric infarction with embolism

1. Once embolism is confirmed at angiography, papaverine infusion is started, then laparotomy should be performed to evaluate bowel viability. Surgical intervention may involve arteriotomy with thrombectomy and bowel resection if nonviable necrotic bowel is found. Postoperative anticoagulation is recommended for all patients.

2. Patients without peritoneal signs with minor emboli, who achieve pain relief with vasodilator infusion, may be managed nonoperatively with repeated angiograms.

D. Acute mesenteric infarction with thrombosis

1. Acute mesenteric ischemia secondary to thrombosis is treated initially with a papaverine infusion started at angiography. Patients without peritoneal signs with minor thrombi may be treated with papaverine only.

2. Patients with major thrombi with good collateral vasculature, without peritoneal signs, may be observed in the hospital without a papaverine infusion. Patients with peritoneal signs and documented thrombosis
Intestinal Obstruction

require laparotomy.

References: See page 108.

Intestinal Obstruction

I. Clinical evaluation
A. Intestinal obstruction is characterized by nausea, vomiting, cramps, and obstipation. Suspected intestinal obstruction requires immediate surgical consultation.

B. Small-bowel obstruction. Auscultation may reveal high-pitched rushes or tinkles that coincide with episodes of cramping. Pain usually is epigastric or periumbilical.

1. Proximal obstruction. Frequent non-bilious vomiting is prominent if the obstruction is proximal to the ampulla of Vater. Colicky pain occurs at frequent intervals (2-5 minutes). Obstipation may not occur until late, and distention is minimal or absent.

2. Distal obstruction. Vomiting is bilious and less frequent. The vomiting may be feculent if the obstruction has been long-standing. Colicky pain occurs at intervals of 10 minutes or more, and it is less intense. Abdominal pain may persist between cramps. Distention increases gradually.

C. Colonic obstruction

1. Colonic obstruction is caused by colon cancer in 60-70% of cases, and diverticulitis and volvulus account for 30%. Obstruction is more common in the left colon than the right.

2. Milder attacks of pain often occur in the weeks preceding the acute episode. Colic is perceived in the lower abdomen or suprapubically, and obstipation and distention are characteristic. Nausea is common, and vomiting may occur.

3. Tenderness is usually mild in uncomplicated colonic obstruction. Rectal examination or sigmoidoscopy may detect an obstructing lesion.

D. Colonic pseudo-obstruction (Ogilvie's syndrome) may occur in the elderly, bedridden, or institutionalized individual, often after recent surgery.

E. Strangulated obstruction is characterized by constant pain, fever, tachycardia, peritonitis, and leukocytosis.

F. Laboratory evaluation of intestinal obstruction

1. Hypokalemic alkalosis is the most common metabolic abnormality resulting from vomiting and fluid loss. Elevated BUN and creatinine suggest significant hypovolemia. Hypochloremic acidosis with increased anion gap may occur with strangulated obstruction.

2. Leukocyte count frequently is normal in uncomplicated obstruction; however, leukocytosis suggests strangulation.

3. Serum amylase may be elevated with bowel infarction.

G. Radiography

1. Plain films

a. Small-bowel obstruction. Plain radiographs may demonstrate multiple air-fluid levels with dilated loops of small intestine, but no colonic gas. Proximal jejunal obstruction may not cause dilatation. Distal obstruction is characterized by a ladder pattern of dilated loops of bowel.

b. Colonic obstruction. Obstructive lesions usually are located in the left colon and rectum and cause distention of the proximal colon. Dilated colon has a peripheral location within the abdomen, and
Acute Pancreatitis

Russell A. Williams, MD

The incidence of acute pancreatitis ranges from 54 to 238 episodes per 1 million per year. Patients with mild pancreatitis respond well to conservative therapy, but those with severe pancreatitis may have a progressively downhill course to respiratory failure, sepsis and death.

I. Etiology
A. Acute pancreatitis is most commonly caused by excessive ethanol intake or cholelithiasis, accounting for 65-80 percent of cases. Alcohol-induced pancreatitis occurs after the patient has consumed large quantities of alcohol. Following alcoholic and gallstone-related pancreatitis, the next largest category is idiopathic pancreatitis. The cause of pancreatitis cannot be determined in 10 percent of patients.
B. Elevation of serum triglycerides (>1,000 mg per dL) has been linked with acute pancreatitis. Autodigestion of the pancreas due to activation of trypsin, causes the pathologic changes found in acute pancreatitis.

II. Clinical presentation

A. Midepigastric pain, nausea and vomiting are the typical symptoms associated with acute pancreatitis. The abdominal pain frequently radiates to the back. The pain is sudden in onset, progressively increases in intensity and becomes constant.

B. Physical examination

1. Patients with acute pancreatitis appear ill. The severity of pain often causes the patient to move continuously in search of a more comfortable position. Findings that suggest severe pancreatitis include hypotension, tachypnea with decreased basilar breath sounds, and flank (Grey Turner's sign) or periumbilical (Cullen's sign) ecchymoses, indicative of hemorrhagic pancreatitis. If fever is present, infection should be ruled out.

2. Abdominal distention and tenderness in the epigastrium are common. Voluntary or involuntary guarding, rebound tenderness, and hypoactive or absent bowel sounds indicate peritoneal irritation.

III. Laboratory tests

A. Leukocytosis with a left shift and an elevated hematocrit (hemoconcentration) and hyperglycemia are common. Prerenal azotemia may result from dehydration. Hypoalbuminemia, hypertriglyceridemia, hypocalcemia, hyperbilirubinemia, and mild elevations of transaminases and alkaline phosphatase are common.

B. Amylase. An elevated amylase level often confirms the clinical diagnosis of pancreatitis.

Selected Conditions Other Than Pancreatitis Associated with Amylase Elevation

C. Lipase measurements are more specific for pancreatitis than amylase levels but less sensitive. Hyperlipasemia may also occur in patients with renal failure, perforated ulcer disease, bowel infarction and bowel obstruction.

D. Abdominal radiographs may reveal non-specific findings of pancreatitis,
Acute Pancreatitis

such as “sentinel loops” (dilated loops of small bowel in the vicinity of the pancreas), ileus and pancreatic calcifications.

E. Ultrasonography demonstrates the entire pancreas in only 20 percent of patients with acute pancreatitis. Its greatest utility is in evaluation of patients with possible gallstone disease.

F. Computed tomography (CT) is the imaging modality of choice in acute pancreatitis. In 14-29% of patients, CT findings will be normal, usually indicating mild disease. Pancreatic necrosis, pseudocysts and abscesses may be detected by CT.

IV. Prognosis. Ranson’s criteria is used to determine prognosis in acute pancreatitis. Patients with two or fewer risk factors have a mortality rate of less than 1 percent; those with three or four risk factors, a mortality rate of 16 percent; five or six risk factors, a mortality rate of 40 percent; and seven or eight risk factors, a mortality rate approaching 100 percent.

Ranson’s Criteria for Acute Pancreatitis

At admission During initial 48 hours

1. Age >65 years 1. Hematocrit drop >10%
2. WBC >16,000 per mm³ 2. BUN rise >5 mg per dL
3. Blood glucose >200 mg per dL 3. Arterial pO₂ <60 mm Hg
4. Serum LDH >350 IU per L 4. Base deficit >4 mEq per L
5. AST >250 U per L 5. Serum calcium <8.0 mg per dL

V. Treatment

A. Most cases of acute pancreatitis will improve within three to seven days. Management consists of prevention of the complications of severe pancreatitis. Vigorous intravenous hydration is necessary because liters of fluid may be sequestered, leading to intravascular depletion, prerenal azotemia and shock. A decrease in urine output to less than 30 mL per hour is an indication of inadequate fluid replacement.

B. Patients should take nothing by mouth to minimize pancreatic secretions. Total parenteral nutrition should be instituted for those patients fasting for more than five days. A nasogastric tube is warranted in patients with nausea and vomiting or ileus.

C. Pain control. The use of morphine is discouraged because it may cause Oddi’s sphincter spasm, which may exacerbate the pancreatitis. Meperidine (Demerol) (25-100 mg IV q4-6h) is favored. Other injectable agents such as ketorolac (Toradol), 60 mg IM/IV, then 15-30 mg IM/IV q6h, are also used.

D. Antibiotics. Routine use of antibiotics is not recommended in most cases of acute pancreatitis. In cases of infectious pancreatitis, treatment with cefotaxin, cefotetan, or ampicillin/subbactam is appropriate.

E. Pseudocyst is suggested by continuing abdominal pain, vomiting, nausea, epigastric tenderness, abdominal mass, and hyperamylasemia. CT is diagnostic. Pseudocysts smaller than 5 cm in diameter will resorb without intervention. Pseudocysts larger than 5 cm usually require surgical intervention after the wall has matured.

F. Alcoholics may require alcohol withdrawal prophylaxis with lorazepam (Ativan) 1-2 mg IM/IV q1-6h as needed x 3 days, thiamine 100 mg IM/IV qd x 3d; folic acid 1 mg IM/IV qd x 3d; multivitamin qd.
Acute Cholecystitis

Russell A. Williams, MD

Acute cholecystitis is a bacterial inflammation of the gallbladder which may cause severe peritonitis. Gallstones are present in the gallbladder in about 95% of cases. The incidence of acute calculous cholecystitis is higher in females, with a female-to-male ratio of 3:1 up to the age of 50 and a ratio of 1.5:1 thereafter.

I. Pathophysiology. Patients who have symptoms from gallstones have an elective cholecystectomy to avoid acute cholecystitis and its complications. Acute calculous cholecystitis is caused by obstruction of the cystic duct by a stone. Positive bacterial cultures of bile or gallbladder wall are found in 50% to 75% of cases.

II. Clinical evaluation

A. Persistent pain in the area of the gallbladder is present in almost every case. Frequently, the pain develops after ingestion of a meal. The pain is usually in the right upper quadrant, the epigastrium, or both.

B. The pain often radiates toward the tip of the scapula. Pain in the right shoulder is present when the diaphragm is irritated by the inflammation.

C. Nausea and vomiting occur in 60% to 70% of patients.

III. Physical examination

A. Fever is present in about 80% of patients. The most common and reliable finding on physical examination is tenderness in the right upper quadrant, the epigastrium, or both. About half of all patients have muscle rigidity in the right upper quadrant, and about one fourth have rebound tenderness.

B. Murphy’s sign, consisting of inspiratory arrest during deep palpation of the right upper quadrant, is not a consistent finding but is almost pathognomonic when present. A mass in the region of the gallbladder is palpable in about 40%.

IV. Laboratory evaluation and imaging studies

A. White blood cell count is elevated in 85% of cases. One half have elevation of the serum bilirubin, and the serum amylase is increased in one third.

B. Radionuclide scan (HIDA scan). The specific test for acute cholecystitis is the HIDA scan. Normally, the scan outlines the liver and the extrahepatic biliary tract, including the gallbladder, and shows the nuclide flowing into the upper small intestine. In acute cholecystitis, the gallbladder is not seen on the scan. Radionuclide has a sensitivity of almost 100% and a specificity of 95%.

C. Ultrasound. Calculi within the gallbladder can be accurately detected by ultrasonography, but this test is not specific for acute calculous cholecystitis. A thickened gallbladder wall and pericholecystic fluid are sometimes present.

V. Differential diagnosis. Acute appendicitis, perforated or penetrating duodenal ulcer, acute or perforated gastric ulcer, and acute pancreatitis. In approximately 15% of cases of acute cholecystitis, the serum amylase is elevated, suggesting the possibility of acute pancreatitis.
VI. Treatment

A. Patients suspected of having acute cholecystitis should be hospitalized. Intravenous crystalloids should be given to restore intravascular volume. Preoperative management should include administration of an antibiotic that is effective against gram-positive and -negative aerobes and anaerobes. Those present most frequently are *Escherichia coli*, *Klebsiella* species, *Streptococcus faecalis*, *Clostridium welchii*, *Proteus* species, *Enterobacter* species, and anaerobic *Streptococcus* species.

B. A second-generation cephalosporin is recommended for most cases of acute cholecystitis and reservation of the triple drug combination for patients who are seriously ill with sepsis. Antibiotic therapy should be initiated as soon as the diagnosis is made and should be continued for 24 hours postoperatively, unless peritonitis is severe, in which case it should continue for 7 days.

1. Ampicillin 1-3.0 gm IV q6h OR
2. Ampicillin-sulbactam (Unasyn) 1.5-3.0 gm IV q6h AND
3. Gentamicin, 1.5-2 mg/kg, then 2-5 mg/kg/d IV.
4. Cefoxitin (Mefoxin) 1-2 gm IV q6-8h.
5. Ticarcillin/clavulanate (Timentin) 3.1 g IV q4-6h.
6. Piperacillin/tazobactam (Zosyn) 4.5 gm IV q6h.
7. Meperidine (Demerol) 50-100 mg IV/IM q4-6h prn pain.

C. The definitive treatment of acute cholecystitis is early laparoscopic cholecystectomy. Operative cholangiography is routinely performed unless the extent of inflammation makes it unsafe.

Laparoscopic Cholecystectomy Procedure

I. Advantages of laparoscopic surgery: Usually less postoperative pain, reduced recovery time; several small puncture wounds instead of a large surgical incision, and early return to work.

II. Contraindications to laparoscopic cholecystectomy: Adhesions, extreme gallbladder scarring, severe acute inflammation, and bleeding.

III. Technique

A. Preoperative antibiotic therapy with cefoxitin (Mefoxin) 1-2 gm IV q6h is usually used routinely. The procedure is performed with the patient under general or epidural anesthesia.

B. The stomach is decompressed with a nasogastric tube to facilitate exposure. With the patient in the supine position, a 2-cm incision is made superior or inferior to the umbilicus. Using S-shaped retractors, the fascia is identified and grasped with a small Kocher or Allis clamp. The fascia is elevated and incised to allow for easy admission of a finger to confirm entrance into the abdominal cavity and sweep away any adhesions. A U-stitch is placed using an absorbable suture. The Hasson cannula is inserted and secured with the suture used for the U-stitch.

C. After setting the insufflator to an insufflation pressure of 12 mm Hg, CO\textsubscript{2} is instilled at a low flow (1 L/min) into the abdominal cavity through the Hasson cannula. Approximately 1 L CO\textsubscript{2} is instilled at a low flow rate, and then the flow rate is adjusted to the maximum (20 L/min). The endoscope is inserted, and the abdominal and pelvic cavities are inspected.

D. The patient is placed in reverse Trendelenburg position to allow the colon and omentum to fall inferiorly. After the pelvis and upper abdomen are visually inspected, a 10-mm cannula is inserted two thirds of the way
84 Open Cholecystectomy Procedure

between the umbilicus and the xiphisternum just to the right of the midline. A 5-mm cannula is inserted 3 cm inferior to the costal margin in the midclavicular line, and a second 5-mm cannula is inserted 4 cm inferior to the costal margin in the midaxillary line. All three cannulas are inserted using a trocar under direct endoscopic vision. The umbilical cannula is used for the endoscope and CO2 inflow, and the epigastric port is used for dissection. Through the most lateral right subcostal cannula, a grasper retracts the dome of the gallbladder over the liver toward the right diaphragm. Through the other subcostal cannula, a grasper retracts the neck of the gallbladder laterally and anteriorly.

E. Adhesions are dissected off of the gallbladder, and dissection is begun at the neck of the gallbladder and proceeds along the cystic duct. After the cystic duct and artery have been identified by removal of the peritoneum overlying these structures, a titanium clip is placed at the junction of the neck and cystic duct. A cholangiogram is performed by partially transecting the cystic duct using scissors. The cholangiocatheter is inserted into the cholecystocholangiography, and a cholangiogram is performed using 30% Renografin.

F. If the cholangiogram is normal, the catheter is removed and the cystic duct is secured just inferior to the ductotomy with two titanium clips and divided. The cystic artery is clipped and divided. The infundibulum and neck of the gallbladder are rotated medially or laterally, and the peritoneal reflection onto the gallbladder is incised using the hook cautery. The gallbladder is dissected from its bed, and before the last attachments at the dome are divided, the gallbladder bed is irrigated and inspected for bleeding and bile leaks. The stumps of the cystic duct and artery are inspected for bleeding and bile leaks.

G. When hemostasis is attained, the remaining attachments between the gallbladder and the liver are divided and the gallbladder is positioned just superior to the liver. The laparoscope and CO₂ insufflation tubing are transferred to the epigastric cannula, and the extraction sack is passed under direct visualization through the umbilical cannula. The sack is opened, and the gallbladder placed in the bag and extracted.

H. The umbilical incision is closed under direct visualization by tying the U-stitch. The subcostal cannulas are removed under direct visualization. The epigastric cannula is positioned over the liver away from the omentum, CO₂ insufflation stopped, and residual CO₂ allowed to escape from the abdomen through the cannula. The cannula is removed, and the incisions are closed with subcuticular stitch and sterile strips. Dressings are placed over the incisions, and the nasogastric tube and Foley catheter are removed. The patient may be discharged after observation. Most patients can be discharged within a few hours.

Open Cholecystectomy Procedure

A. After induction of anesthesia place a nasogastric tube to decompress the stomach. The most commonly used incision is Kocher's right subcostal. Place incision 4 cm below and parallel to the costal margin, and extend it from the midline to the anterior axillary line. Open the anterior rectus sheath with a knife in the line of the incision. Divide the rectus muscle with cautery, and open the peritoneum between forceps.

B. Systematically explore the peritoneal cavity and note the appearance of
Palpate the gallbladder from the ampulla towards the fundus, then palpate the common duct, noting any dilation or foreign bodies. Carefully palpate the colon for neoplasms.

C. Grasp the gallbladder with a Rochester-Pean clamp near the fundus. Hold forceps in one hand, and introduce the right hand over the right lobe of the liver, permitting the liver to descend. Divide any adhesions to the omentum colon or duodenum, and place a pack over these structures. Retract the structures inferiorly with a broad-bladed Deaver's retractor.

D. Inspect the anatomy of the biliary tree by carefully dividing the peritoneum covering the anterior aspect of the cystic duct, and continue dissecting into the anterior layer of the lesser omentum overlying the common bile duct. Bluntly dissect with a dissector (Kitner), exposing Charcot's triangle bounded by the cystic duct, common bile duct and inferior border of the liver. The cystic artery should be seen in this triangle. Carefully observe the arrangement of the duct system and arterial supply. Do not divide any structure until the anatomy has been identified, including the cystic duct and common bile duct.

E. Pass a ligature around the cystic duct with a right-angle clamp, and make a loose knot near the common duct. Partially divide the cystic duct below the infundibulum, and place a small polyethylene catheter attached to a syringe filled with saline into the cystic duct for 1-2 cm. Tighten the ligature holding the catheter in position.

F. Attach a second syringe containing contrast material to the catheter, and remove all instruments. Place a sterile sheet, and slowly inject 10-15 cc of diluted dye into the common duct. An operative cholangiogram should be performed to detect stones and evaluate the duct system.

G. Palpate the lower end of common bile duct, pancreas, and the foramen of Winslow. Palpate the ampulla, checking for stones or tumor. Hold the forceps on the gallbladder in the left hand, and clear the cystic artery of soft tissue with a pledget held in forceps. Follow the artery to the gallbladder, and clamp it with a right angle clamp. Divide and ligate the artery close to the edge of the gallbladder, using clips or 000 silk.

H. Reaffirm the junction of the cystic duct with the common bile, then completely divide the exposed cystic duct, leaving a stump of 5 mm.

I. Incise the peritoneum anteriorly over the gallbladder with a scalpel. Elevate the peritoneum from the gallbladder, and separate the gallbladder gently with sharp and blunt dissection. Tissue strands containing vessels should be cauterized before division.

J. Inspect the gallbladder bed for bleeding and cauterize and/or ligate any bleeding areas. Control any persistent oozing from the bed with a small pack of hemostatic gauze.

K. Irrigate the site with saline. If there is excessive fluid present, place a soft rubber Penrose drain or closed suction drain in the area of the dissection, and bring it out through a separate stab wound in the right upper quadrant. Inspect the operative field, including the ligatures on the arteries and the cystic duct. Approximate the peritoneum with continuous nonabsorbable suture.

L. Irrigate the wound with saline and approximate the rectus fascia and fascia of the oblique muscles with interrupted, nonabsorbable sutures. Irrigate the subcutaneous space with saline, and close the skin with staples, or absorbable subcuticular sutures.
Choledocholithiasis

Choledocholithiasis results when gallstones pass from the gallbladder through the cystic duct into the common duct.

I. Clinical evaluation
   A. Patients with choledocholithiasis generally present with jaundice. The patient may have pain or symptoms from associated biliary colic or acute cholecystitis.
   B. Physical examination. Icterus is typical unless there is associated acute cholecystitis. Ultrasonography can demonstrate gallstones in the gallbladder and in the common bile duct in 20-50% of patients with choledocholithiasis.
   C. The diagnosis depends on demonstrating enlarged common bile and intrahepatic ducts associated with abnormal liver function tests.
   D. Alkaline phosphatase and bilirubin are usually elevated.
   E. Ultrasound may reveal a dilated common bile duct, and stones may be seen. Frequently, gallstones in the lower common bile duct cannot be demonstrated by ultrasonography because of overlying bowel gas.
   F. Endoscopic retrograde cholangiopancreatography (ERCP) or percutaneous transhepatic cholangiography (PTC) are often used to confirm the diagnosis. These tests can opacify the biliary tree and demonstrate intraductal stones.

II. Management of choledocholithiasis
   A. All jaundiced patients and those known to have many, large, or intrahepatic stones should have preoperative ERCP to rule out malignancy and retrieve the stones.
   B. Preoperative ERCP with sphincterotomy should be performed in all patients who are at high risk of common bile duct stones or in whom common bile duct stones have been demonstrated. Laparoscopic cholecystectomy may be completed later.
   C. If ERCP is unsuccessful at clearing the common bile duct, the patient may require a laparoscopic or open cholecystectomy.
Breast Cancer Screening

Breast cancer is the most common form of cancer in women. There are 200,000 new cases of breast cancer each year, resulting in 47,000 deaths per year. The lifetime risk of breast cancer is one in eight for a woman who is age 20. For patients under age 60, the chance of being diagnosed with breast cancer is 1 in about 400 in a given year.

I. Pathophysiology

A. The etiology of breast cancer remains unknown, but two breast cancer genes have been cloned—the BRCA-1 and the BRCA-2 genes. Only 10% of all of the breast cancers can be explained by mutations in these genes.

B. Estrogen stimulation is an important promoter of breast cancer. Early menarche and late menopause are risk factors for breast cancer. Late age at birth of first child or nulliparity also increase the risk of breast cancer.

C. Family history of breast cancer in a first degree relative and history of benign breast disease also increase the risk of breast cancer.

II. Diagnosis and evaluation

A. Clinical evaluation of a breast mass should assess the duration of the lesion, associated pain, relationship to the menstrual cycle or exogenous hormone use, and change in size on discovery. The presence of nipple discharge and its character (bloody or tea-colored, unilateral or bilateral, spontaneous or expressed) should be assessed.

B. Menstrual history. The date of last menstrual period, age of menarche, age of menopause or surgical removal of the ovaries, regularity of the menstrual cycle, previous pregnancies, age at first pregnancy, and lactation history should be determined.

C. History of previous breast biopsies, breast cancer, or cyst aspiration should be investigated. Previous or current hormone replacement therapy
88 Breast Cancer Screening

and dates and results of previous mammograms should be ascertained.

D. Family history should document breast cancer in relatives and the age at which family members were diagnosed.

III. Physical examination

A. The breasts should be inspected for asymmetry, deformity, skin retraction, erythema, peau d’orange (indicating breast edema), and nipple retraction, discoloration, or inversion.

B. Palpation

1. The breasts should be palpated while the patient is sitting and then supine with the ipsilateral arm extended. The entire breast should be palpated systematically.

2. The mass should be evaluated for size, shape, texture, tenderness, and fixation to skin or chest wall. The location of the mass should be documented with a diagram in the chart. The nipples should be expressed to determine whether discharge can be induced. Nipple discharge should be evaluated for single or multiple ducts, color, and any associated mass.

3. The axillae should be palpated for adenopathy. Enlarged lymph nodes should be assessed for size, number, and fixation. The supraclavicular and cervical nodes should also be assessed.

IV. Breast imaging

A. Mammography

1. Screening mammography is performed in the asymptomatic patient and consists of two views. Patients are not examined by a mammographer. Screening mammography reduces mortality from breast cancer and should usually be initiated at age 40.

2. Diagnostic mammography is performed after a breast mass has been detected. Patients usually are examined by a mammographer, and films are interpreted immediately and additional views of the lesion are completed. Mammographic findings predictive of malignancy include spiculated masses with architectural distortion and microcalcifications. A normal mammography in the presence of a palpable mass does not exclude malignancy.

B. Ultrasonography is used as an adjunct to mammography to differentiate solid from cystic masses. It is the primary imaging modality in patients younger than 30 years old.

V. Methods of breast biopsy

A. Stereotactic core needle biopsy. Using a computer-driven stereotactic unit, the lesion is localized in three dimensions, and an automated biopsy needle obtains samples. The sensitivity and specificity of this technique are 95-100% and 94-98%, respectively.

B. Palpable masses. Fine-needle aspiration biopsy (FNAB) has a sensitivity ranging from 90-98%. Nondiagnostic aspirates require surgical biopsy.

1. The skin is prep with alcohol and the lesion is immobilized with the nonoperating hand. A 10 mL syringe, with a 18 to 22 gauge needle, is introduced to the central portion of the mass at a 90° angle. When the needle enters the mass, suction is applied by retracting the plunger, and the needle is advanced. The needle is directed into different areas of the mass while maintaining suction on the syringe.

2. Suction is slowly released before the needle is withdrawn from the mass. The contents of the needle are placed onto glass slides for pathologic examination.
Breast Cysts

C. Nonpalpable lesions

1. Needle localized biopsy
   a. Under mammographic guidance, a needle and hookwire are placed into the breast parenchyma adjacent to the lesion. The patient is taken to the operating room along with mammograms for an excisional breast biopsy.
   b. The skin and underlying tissues are infiltrated with 1% lidocaine with epinephrine. For lesions located within 5 cm of the nipple, a periareolar incision may be used or use a curved incision located over the mass and parallel to the areola. The skin and subcutaneous fat are incised, then the lesion is palpated and the mass is excised.
   c. After removal of the specimen, a specimen x-ray is performed to confirm that the lesion has been removed. The specimen can then be sent fresh for pathologic analysis.
   d. The subcutaneous tissues should be closed with a 4-0 chromic catgut suture, and the skin should be closed with 4-0 subcuticular suture.

References: See page 108.

Breast Cysts

I. Clinical evaluation
   A. A breast cyst is palpable as a smooth, mobile, well-defined mass. If the cyst is tense, the texture may be very firm, resembling a cancer. Aspiration will determine whether the lesion is solid or cystic. Breast cyst fluid may vary from straw-colored to dark green. Cytology is not routinely necessary. The cyst should be aspirated completely.
   B. If a mass remains after drainage or if the fluid is bloody, excisional biopsy is indicated. If no palpable mass is felt after drainage, the patient should be reexamined in 3-4 weeks to determine whether the cyst recurs. Recurrent cysts can be re-aspirated. Repeated recurrence of the cyst requires an open biopsy to exclude intracystic tumor.
   C. Nonpalpable cysts. If the cyst wall is seen clearly seen on ultrasound and there is no interior debris or intracystic tumor, these simple cysts do not need to be aspirated. Any irregularity of the cyst wall or debris within the cyst requires a needle localized biopsy.

Fibroadenomas

I. Clinical evaluation
   A. Fibroadenomas frequently present in young women as firm, smooth, lobulated masses that are highly mobile. They have a benign appearance on mammography and are solid by ultrasound.
   B. A tissue diagnosis can be obtained by fine needle aspiration biopsy or excisional biopsy.

II. Management of fibroadenomas
   A. Fibroadenomas may be followed conservatively after the diagnosis has been made. If the mass grows, it should be excised.
   B. Large fibroadenomas (>2.5 cm) should usually be excised. Often
Breast Cancer

Fibroadenomas will grow in the presence of hormonal stimulation, such as pregnancy.

Breast Cancer

The initial management of the breast cancer patient consists of assigning a clinical stage based on examination. The stage may be altered once the final pathology of the tumor has been determined. Staging of breast cancer is based on the TNM staging system.

I. Preoperative staging in stage I and II breast cancer: Preoperative workup should include a CBC, SMA18, and chest x-ray. If elevated alkaline phosphatase or hypercalcemia is present, a bone scan should be completed. Abnormal liver function tests should be investigated with a CT scan of the liver.

II. Surgical options for stage I and II breast cancer

A. Breast conservation therapy (BCT) has been shown to result in survival and local recurrence rates equivalent to modified radical mastectomy; therefore, breast conservation is the preferred therapy for stage I and II breast cancer. The technique includes lumpectomy, axillary lymph node dissection, and breast irradiation.

1. Contraindications to BCT
   a. Contraindications to radiotherapy (i.e., prior breast irradiation, ongoing pregnancy)
   b. Steroid-dependent collagen vascular disease
   c. Tumor-breast ratio that would result in an unacceptable cosmetic result (e.g., a large tumor in a small breast)
   d. Diffuse, malignant microcalcifications on mammography
   e. Tumor greater than 5 cm in diameter

2. Lumpectomy technique. Incisions should be curvilinear and parallel with the nipple. A gross margin of 1 cm should be removed. The lumpectomy specimen is given immediately to the pathologist for inking and for an assessment of the gross margins. Subcutaneous tissue is closed, and the skin is approximated with a subcuticular suture.

3. Follow-up following BCT consists of a physical examination every 3-4
92 Breast Cancer

months for the first 3 years, every 6 months for the next 2-3 years, then yearly. A SMA18 and CBC are done at each visit and a chest x-ray is done yearly.

A. A posttreatment mammography of the treated side is done 6 months after the completion of radiotherapy, then every 6 months for the first 2 years, followed by annual mammograms. Yearly mammography should be performed on the opposite breast.

B. Modified radical mastectomy consists of a total mastectomy and an axillary node dissection. Instaging axillary lymphadenectomy, levels I and II are removed routinely. Reconstruction of the breast should be offered to all patients undergoing mastectomy. Physical examination schedule and blood work are the same as for lumpectomy. The chest wall should be examined for recurrence. Mammography of the opposite breast should continue yearly.

III. Locally advanced breast cancer (LABC) consists of T3N0 (stage IIB), IIIA, and IIIB breast cancer. All LABC patients should undergo staging with CBC, SMA18, bone scan, and CT scan of chest and abdomen.

A. Noninflammatory LABC. Multimodality therapy consists of neoadjuvant chemotherapy (ie, given before surgery), modified radical mastectomy, radiotherapy to the chest wall, axilla and supraclavicular nodes, and further chemotherapy.

B. Inflammatory LABC (T4d). Inflammatory breast cancer is characterized by erythema of the skin, skin edema, warmth, tenderness, and an underlying tumor mass. Treatment requires aggressive multi-modality therapy.

C. Follow-up. Patients should be followed closely because they are at higher risk of local and distant recurrence.

IV. Ductal carcinoma in situ (DCIS) consists of Tis, stage 0 lesions. These lesions consist of malignant ductal cells that have not penetrated the basement membrane. DCIS is a precursor of invasive ductal cancer.

A. Physical examination is usually normal with DCIS. The most common presentation is suspicious microcalcifications on mammography. DCIS can cause a nipple discharge or a palpable mass.

B. Surgical therapy

1. BCT. Lumpectomy and adjuvant radiotherapy are an alternative to mastectomy in well-localized DCIS when negative microscopic margins can be obtained.

2. Total mastectomy, including removal of the nipple areolar complex and breast tissue, results in survival rates of 98-99%. An axillary dissection is not done routinely because the chance of nodal involvement is only 1-2%.

References: See page 108.
Prostate Cancer

The average age at diagnosis of prostate cancer is 73 years. The prevalence of prostate cancer is 30% in men over the age of 50. One in six men will be diagnosed with prostate cancer during their lifetimes.

I. Clinical evaluation

A. Some patients with prostate cancer may have obstructive urinary symptoms similar to benign prostatic hypertrophy; some patients may have weight loss and bone pain. Most patients have no symptoms, only an elevated prostate specific antigen found on routine screening.

B. Physical exam. Digital rectal exam is used to assess the prostate nodule for extension beyond prostate edge, firmness, fixation, or induration.

C. Prostate specific antigen (PSA)

1. Prostate specific antigen (PSA) is a glycoprotein specific for prostate tissue (although not necessarily prostate cancer). Elevated serum levels of PSA correlate closely with an increased likelihood of prostate cancer, especially when increases from baseline levels are observed. An elevated age-specific PSA level is usually an indication to consider transrectal ultrasonography and biopsy of the prostate.

2. PSA screening detects prostate cancer at an earlier stage. However, an improvement in survival has not been documented.

3. Free/total PSA ratio. If the free/total ratio is less than 10%, there is a 67% chance the patient will have prostate cancer. If the free/total ratio is greater than 20%, there is a 10% risk that the patient will have prostate cancer. The PSA ratio is used to assess patients with a PSA in the range of 4-10 (the “grey zone”).

D. Transrectal ultrasonography is more sensitive than digital rectal exam, but still misses 30% of cancers. The main indication for transrectal ultrasonography is to guide transrectal prostate biopsy.
II. Urological evaluation of suspected prostate cancer

A. The prostate nodule should be evaluated by transrectal ultrasound and prostate needle biopsies.

B. Indications for biopsy: (1) Abnormal digital rectal exam (discrete, firm nodule), or (2) elevated prostate-specific antigen (regardless of digital rectal exam).

C. Metastatic evaluation consists of a SMA 18, chest x-ray, intravenous pyelogram or ultrasound (optional), and a bone scan.

III. Staging of prostate cancer

A, B
Renal Colic

| C | Stage III | T3 and Any |
| D | Stage IV | T4 or N or M Any and |

### Therapy of early stage prostate cancer

A. Stage 0 disease can be followed.
B. Stage I and II disease are best managed surgically with radical prostatectomy or radiation therapy. Radical prostatectomy consists of removal of the prostate and seminal vesicles, and a staging pelvic lymph node dissection.
C. Stage III disease is managed with radiotherapy or surgery.
D. Stage IV disease is managed with endocrine manipulation.
E. There is no firm evidence that any of these therapies is better than any other; therefore, “watchful waiting” is also a legitimate option in selected patients.

F. **Endocrine therapy of advanced prostate carcinoma.** Treatment of stage IV prostate cancer involves surgical or medical castration. Total blockade with leuprolide (Lupron) plus flutamide (Eulexin) is slightly better than leuprolide alone. Orchiectomy is an outpatient procedure that is the safest and least expensive option. The incidence of impotence with orchiectomy is no different than with medical castration therapies.

**References:** See page 108.

### Renal Colic

Approximately 5% of the U.S. population will pass a urinary tract stone during their lifetime.

**I. Pathophysiology**

A. Calcium-containing stones are the most common (70%).
B. Magnesium-ammonium-phosphate stones, also known as struvite stones, are almost always associated with urinary tract infection with urea-splitting bacteria, such as Proteus mirabilis.
C. Uric acid stones are less common and are radiolucent, making diagnosis by plain films alone difficult.
D. Cystine stones are rare and associated with cystinuria, a rare autosomal recessive hereditary disorder.

**II. Clinical evaluation**

A. Renal colic is characterized as severe colicky pain that is intermittent and usually in the flank or lower abdomen. Patients usually cannot find a “comfortable position,” and the pain often radiates to the testes or groin. A history of previous stones, poor fluid intake, urinary tract infections, or hematuria is common.
B. Obstruction located at the ureteropelvic junction causes pure flank pain, while upper ureteral obstruction causes flank pain that radiates to the groin. Midureteral stones cause lower abdominal pain and may mimic appendicitis or diverticulitis, but without localized point tenderness or guarding. Lower ureteral stones may cause irritative voiding symptoms and scrotal or labial pain.
Renal Colic

C. Patients with nephrolithiasis generally complain of nausea and vomiting. They commonly have gross or microscopic hematuria, fever, and an increased white blood cell count may. Prior episodes of renal colic or a family history of renal stones is often reported.

D. Physical examination
1. Generally the patient is agitated, diaphoretic, and unable to find a comfortable position.
2. Hypertension and tachycardia are common.
3. Costovertebral angle tenderness is the classic physical finding; however, minimal abdominal tenderness without guarding, rebound or rigidity may be present. Right or left lower quadrant tenderness or an enlarged kidney may sometimes be noted.

IV. Laboratory evaluation
A. A urinalysis with microscopic, serum electrolytes, BUN, creatinine, complete blood count, and urine culture should be obtained. An elevated white blood cell count may be noted. A significant number of white cells in the urine also suggests infection.
B. A plain abdominal film may demonstrate a calcification along the course of the urinary tract. Ninety percent of all calculi are radiopaque. Calcifications are frequently obscured by overlying bowel gas.
C. Intravenous pyelogram. IVP is the gold standard for the diagnosis of urolithiasis, and it allows rapid assessment of the degree of obstruction, location of the stone and any renal function impairment. Acute ureteral obstruction may appear as a dense nephrogram with a delay in excretion of contrast.
D. Ultrasound may be useful in patients with renal failure or an intravenous contrast allergy.

V. Management of renal calculi
A. Most renal calculi will pass spontaneously, and only expectant management with hydration and analgesia is necessary. Obstruction associated with fever indicates urinary tract infection, and it requires prompt drainage with either a ureteral stent or percutaneous nephrostomy.
B. Indications for admission
1. High fever, uncontrollable pain
2. Intractable nausea and vomiting with an inability to tolerate oral fluids
3. Solitary kidney
C. Inpatient management
1. Vigorous intravenous hydration and intravenous antibiotics are important when infection is suspected. Parenteral narcotics are often necessary.
2. Ketorolac (Toradol), 60 mg IM/IV, then 15-30 mg IM/IV q6h, is effective and provides a good alternative to narcotics.
3. Strain all urine in an attempt to retrieve spontaneously passed stones for X-ray crystallographic analysis.
4. Stones measuring 5 to 10 mm have a decreased likelihood of passage, and early elective intervention should be considered.
5. Extracorporeal shock-wave lithotripsy (ESWL) is the most common procedure for small renal or ureteral stones. Eighty percent of patients become stone-free after one treatment.
6. Ureteroscopy with laser, ultrasound or electrohydraulic lithotripsy may
be used as well. Open surgical stone removal is rarely necessary.

D. Outpatient management
1. Most patients with renal colic do not require admission. The majority of stones measuring less than 4 mm will pass spontaneously (90-95%), and 80% of these will pass within 4 weeks.
2. Patients should increase intake of oral fluids, take narcotic pain medication, and strain all urine. Plain abdominal films may be used to assess movement of the stone.

E. Follow-up care
1. After the stone has passed, a metabolic evaluation is important because 70% of patients will have repeat stones if not diagnosed.
2. Evaluation may include chemistry screening, calcium, uric acid, phosphorous, urine cystine (nitroprusside test), 24 hour urine collection for uric acid, calcium, creatinine.

References: See page 108.

Urologic Emergencies

I. Acute urinary retention
A. Acute urinary retention is characterized by a sudden inability to void. It often presents with suprapubic pain and severe urgency. There is usually a history of preexisting obstructive voiding symptoms related to bladder outlet obstruction or poor detrusor function.
B. Benign prostatic hyperplasia is the most common cause of acute urinary retention in men over the age of 50.
1. Patients present with progressively worsening voiding difficulties, resulting in bladder overdistention and subsequent urinary retention.
2. Prostate size on digital rectal examination has no bearing on the degree of outlet obstruction because minimal enlargement of the prostate can cause significant obstruction.
C. Prostate cancer accounts for 25% of patients with acute urinary retention. Ten percent of patients with prostate cancer initially present with bladder outlet obstruction.
D. Additional causes of acute urinary retention include urethral strictures, bladder neck contractures, bladder stones, and acute bacterial prostatitis. Acute urinary retention may be caused by prolonged obstruction, diabetes mellitus, neurologic disorders (spinal cord injury, herniated vertebral disk), and medications.
E. Urinary retention after surgery sometimes temporarily develops in elderly men. Preexisting bladder dysfunction or outlet obstruction is usually present.
F. Anticholinergic medications (antihistamines, antidiarrheals, antispasmodics, tricyclic antidepressants) can suppress bladder function. Sympathomimetic drugs (decongestants and diet pills) that cause contraction of the bladder neck can precipitate an increase in outlet resistance.
G. Complications of acute urinary retention include postobstructive diuresis, bladder mucosal hemorrhage, hypotension, sepsis, renal failure, and autonomic bladder hyporeflexia
H. Clinical evaluation of acute urinary retention
1. Retention is characterized by an inability to void and suprapubic discomfort. A progressive history of difficulty voiding and irritative
voiding symptoms, such as frequency, nocturia or urgency is often noted.

2. Some patients are incontinent as a result of extreme overdistention of the bladder. A past history of gonorrhea, trauma, underlying diseases, or medications should be sought.

3. Palpate for a distended bladder and assess size and consistency of the prostate. Tenderness of the prostate on rectal examination suggests acute prostatitis; a diffusely hard or nodular prostate suggests carcinoma.

4. The penis should be examined to rule out phimosis, paraphimosis, or meatal stenosis. A neurologic exam should include anal sphincter reflex and perineal sensation.

5. Laboratory evaluation. Serum electrolytes, blood urea nitrogen (BUN), creatinine, urinalysis, and urine culture.

I. Management of acute urinary retention

1. The entire bladder contents should be drained with a Foley catheter. Adequate volume replacement is necessary to prevent hypotension.

2. Lubrication with 2% lidocaine jelly (injected directly into the urethra with a syringe) will facilitate insertion of a urethral catheter. Medium-sized catheters (#18 to #22 French) should be used because they tend to be stiffer and easier to insert than smaller ones.

3. In patients with large prostates, Coude catheters (which have a curved tip) may be helpful. The curve of the Coude catheter should be directed superiorly. Other methods of drainage include urethral sounds, filiforms with followers, and percutaneous suprapubic tubes.

4. Admission to the hospital is not required for most patients with acute urinary retention unless infection or renal failure are present. Most patients can be managed with a Foley catheter and discharged home with oral antibiotics and a leg urine bag.

II. Testicular torsion

A. Testicular torsion is an emergency. Delay in treatment may result in testicular loss. A four- to six-hour delay may impair normal testicular function. Torsion can occur at any age; however, it is most common in adolescents, peaking at the age of 15 to 16 years.

B. Testicular torsion presents with sudden onset of pain and swelling in one testicle, occasionally associated with minor trauma. Nausea, vomiting, and lower abdominal or flank pain are common. A history of previous similar episodes with spontaneous resolution is common.

C. A urinalysis is essential in differentiating testicular torsion from epididymitis; however, a negative urinalysis does not rule out epididymitis.

D. Differential diagnosis of testicular torsion

1. Epididymitis due to Neisseria gonorrhoeae and Chlamydia trachomatis is much more common than torsion in adult men.

2. Torsion of an appendix testis or appendix epididymis may mimic testicular torsion. Torsion of the appendix testis may manifest as a tender, pea-sized nodule at the upper pole of the testicle with a small blue-black dot seen through the scrotal skin (the blue dot sign). Management is conservative; however, if there is diagnostic uncertainty, surgical exploration is required.

3. Other less common conditions that may present similarly to torsion include acute hemorrhage into a testicular neoplasm, orchitis, testicular abscess, incarcerated hernia, and testicular rupture.
E. Physical examination
1. Testicular torsion usually presents with severe unilateral testicular pain with an acute onset. The pain is associated with an extremely tender testicle with a transverse lie or an anterior epididymis that lies high in the scrotum.
2. With testicular torsion, the testis is usually high in the scrotum (Brunzel's sign). The presence of a cremasteric reflex almost always rules out testicular torsion.
3. Relief of pain by elevation of the affected testis (Prehn’s sign) suggests epididymitis. A negative Prehn’s sign suggests testicular torsion.
F. Diagnostic imaging. Diagnostic testing should not delay surgical exploration in acute torsion. If the diagnosis is unclear, diagnostic tests may be useful. Color Doppler ultrasound is the most valuable diagnostic study, with nearly a 100% sensitivity and specificity.
G. Management of testicular torsion
1. Immediate detorsion is imperative for all cases of testicular torsion. Testicular salvage rates decrease to 50% at 10 hours and to 10-20% at 24 hours.
2. Manual detorsion can be attempted as an urgent measure by rotating the testicle medially about its pedicle. Surgical orchiopexy is still required.
3. If an infarcted testicle is noted during surgical exploration, it should be removed. If the testicle is viable, both testicles should be fixed in the scrotum with nonabsorbable sutures.

III. Priapism
A. Priapism is defined as a prolonged penile erection. Most cases of priapism in adults are idiopathic. In children the most common causes are sickle cell anemia, hematologic neoplasms (leukemia), and trauma.
B. Evaluation of priapism
1. Patients usually complain of a persistent, painful erection. They may have fever and voiding difficulties.
2. Physical examination should include a neurologic evaluation and perineal inspection for neoplasms. Examination of the penis usually reveals a flaccid glans despite a rigid corpora cavernosa. Hematologic studies should be performed to rule out sickle cell anemia and leukemia.
C. Treatment of priapism
1. Early treatment reduces the risk of long-term impotence, which may occur in 50%. Discomfort can be reduced with parenteral narcotic analgesics and sedation. Detumescence may be achieved using cold compresses, ice packs, warm- or cold-water enemas, and prostate massage.
2. If these treatments are unsuccessful, the static blood may be aspirated from the corpora using a large bore needle. Followed by irrigation of the corpora with saline containing a vasoconstricting agent (phenylephrine, epinephrine, or metaraminol).
3. If this process fails to achieve detumescence, a shunt may be created between the affected corpora cavernosa and unaffected corpus...
spongiosum with a Tru-Cut biopsy needle. When priapism is secondary to sickle cell anemia, therapy also includes hydration, oxygen, and blood transfusion.

References: See page 108.
Peripheral arterial occlusive disease (PAD) is characterized by intermittent claudication, consisting of exercise-induced lower extremity pain relieved by rest. Claudication occurs when the blood supply is inadequate to meet the demand of lower limb muscles, usually resulting from atherosclerotic arterial stenosis.

I. Pathophysiology
   A. The incidence of claudication rises sharply between ages 50 and 75 years, particularly in persons with coronary artery disease. This condition affects at least 10% of persons over 70 years of age and 2% of those 37-69 years of age.
   B. Risk factors. Cigarette smoking is the most important risk factor for PAD. Seventy to 90% of patients with arterial insufficiency are smokers. Risk remains increased for up to 5 years after smoking cessation. Other risk factors include hyperlipidemia, diabetes mellitus, and hypertension.
   C. After five years, 4% of patients with claudication lose a limb and 16% have worsening claudication or limb-threatening ischemia. The five-year mortality rate for patients with claudication is 29%; 60% of deaths result from coronary artery disease, 15% from cerebrovascular disease, and the remainder result from nonatherosclerotic causes.

II. Clinical evaluation of claudication
   A. Evaluation consists of determining the location, extent, and severity of disease and the degree of functional impairment.
   B. Claudication
      1. The key clinical features of claudication are reproducibility of muscular pain in the thigh or calf after a given level of activity and cessation of pain after a period of rest.
      2. Patients should be asked about the intensity of claudication, its location, and the distance they have to walk before it begins.
      3. Aortoiliac disease is manifest by discomfort in the buttock and/or thigh and may result in impotence and reduced femoral pulses. Leriche's syndrome occurs when impotence is associated with bilateral hip or thigh claudication.
      4. Iliofemoral occlusive disease is characterized by thigh and calf claudication. Pulses are diminished from the groin to the foot.
      5. Femoropopliteal disease usually causes calf pain. Patients have normal groin pulses but diminished pulses distally.
      6. Tibial vessel occlusive disease may lead to foot claudication, rest pain, non-healing wounds, and gangrene.
      7. Rest pain consists of severe pain in the distal portion of foot due to ischemic neuritis. The pain is deep and unremitting, and it is exacerbated by elevation of the foot; and the pain is relieved by dangling the affected foot over the side of the bed.
102 Peripheral Arterial Disease

III. Physical examination
A. Evaluation of the peripheral pulses should include the femoral, popliteal, posterior tibial, and dorsalis pedis arteries.
B. Other signs of chronic arterial insufficiency include brittle nails, scaling skin, hair loss on the foot and lower leg, cold feet, cyanosis, and muscle atrophy. The feet should be inspected for skin breakdown or ulceration.
C. Bruits may be auscultated distal to the arterial obstruction.
D. Abdominal examination for a “pulsatile mass” should be performed because of the association between abdominal aortic aneurysm and peripheral arterial disease.

IV. Differential diagnosis
A. Neurogenic claudication (spinal stenosis)
   1. Neurogenic claudication is the clinical syndrome most difficult to distinguish from claudication. Neurogenic claudication is caused by osteophytic narrowing of the neural canal around the spinal nerves.
   2. This syndrome causes radicular leg pain that begins with a change in posture and is relieved by assuming the recumbent position. The leg pain is often accompanied by tingling and numbness.
   3. The pain of neurogenic claudication persists even after the patient has stopped walking or occurs with mere standing or after prolonged sitting. The distance walked until the onset of pain varies with neurogenic claudication.
B. Nocturnal muscle cramps occur in older persons, but the cramps are not related to exercise.
C. Osteoarthritis of the hip may mimic thigh and buttock claudication. However, osteoarthritic pain occurs with variable amounts of exercise, and the pain changes in severity from day to day.

V. Laboratory testing of arterial disease
A. Ankle-brachial index (ABI)
   1. The ankle-brachial index (ABI) is the ratio of ankle systolic blood pressure to arm systolic blood pressure. It is highly sensitive and specific for peripheral arterial disease in nondiabetic patients.
      a. >1.0 is considered normal
      b. 0.4-0.1 suggests arterial obstruction with claudication
      c. <0.4 suggests significant arterial obstruction with critical ischemia (i.e., non-healing wounds or rest pain).
   2. Patients occasionally have normal ABIs at rest, but their symptoms strongly suggest claudication. In these patients, ABIs should be obtained before and after exercise.
   3. ABI and segmental blood pressure measurements are not accurate in patients with calcified vessels (especially diabetics) because ankle blood pressure readings tend to be falsely elevated.
B. Color Doppler imaging is a good diagnostic alternative for patients at high risk for calcification of vessels.
C. Arteriography is indicated following evaluation of ABIs if a patient with claudication is to undergo surgical or endovascular treatment.
D. Magnetic resonance angiography has superior sensitivity over conventional angiography in detecting disease in distal runoff vessels.

VI. Management of peripheral arterial disease
A. Risk factor modification
   1. Cigarette smoking is the most important modifiable risk factor. Claudication patients who abstain from tobacco usually do not progress to limb loss, whereas 11.3% of the patients who continue
smoking require amputation.

2. **Meticulous care of skin** of the lower limbs helps avoid ulcer formation and skin infection.

3. **Obese patients** should be advised to lose weight through exercise and diet.

4. **Hypertension** should be vigorously treated. Beta-blockers do not usually worsen claudication.

5. **Hyperlipidemia.** Regression of femoral atherosclerosis is possible with lipid-lowering therapy. The goal should be to lower the low-density lipoprotein cholesterol level to below 100 mg/dL.

6. **Diabetes** should be aggressively controlled.

B. **Coronary and carotid artery disease assessment** is essential because coronary disease accounts for 60% of deaths.

C. **Hormone replacement therapy** after menopause may slow the progression of atherosclerosis.

D. **Progressive exercise training.** Patients who have intermittent claudication, but no rest pain or ischemic ulceration, should begin a walking program. Patients should walk to or through the onset of claudication for 30 minutes every day.

E. **Pharmacologic management**

1. Cilostazol (Pletal), 100 mg bid, has antiplatelet and vasodilating properties and has been shown to improve treadmill performance and functional status. Contraindicated in heart failure. Side effects include headaches and soft stools.

2. **Aspirin** has no effect on claudication, but because of the high incidence of cerebrovascular and cardiovascular disease, aspirin 160 mg per day, should be given.

F. **Operative and endovascular procedures**

1. Most patients with claudication respond to conservative therapy. Surgery is reserved for patients with rest pain or tissue loss. Patients who have intermittent calf claudication alone are not surgical candidates unless the claudication severely limits their lifestyle or occupational functioning.

2. Patients with rest pain, tissue loss as a result of gangrene, or non-healing ulcers with an ABI less than 0.6 are surgical candidates.

3. Percutaneous transluminal angioplasty has a greater than 90% success rate in the treatment of short-segment aortoiliac occlusive disease, and these results may be improved with the placement of an intra-arterial stent. However, five-year patency rates are only 40-60%.

4. Surgical bypass therapy is an effective treatment for claudication; however, it is associated with 5% morbidity and mortality rates. Aortobifemoral grafting has a 90% 5-year patency rate. Aortoiliac, femoral-femoral crossover, and reversed and in-situ saphenous vein bypass grafting from the common femoral to the popliteal artery have 60-70% 5-year patency rates. An synthetic polytetrafluoroethylene graft (PTFE) is indicated for above knee femoral-popliteal bypass, and it has a 50% 5-year patency rate.

G. **Axillofemoral bypass** is useful for high risk, elderly patients who are unable to tolerate an aortic procedure.

VII. **Management of the acutely threatened limb.** An acutely occluded artery can cause limb loss within hours. The patient will complain of sudden onset of severe unremitting rest pain. Atrial fibrillation often may cause acute embolic arterial occlusion. These patients require emergency
Abdominal Aortic Aneurysms

S.E. Wilson, MD

Abdominal aortic aneurysms (AAAs) are the most common type of arterial aneurysm. Approximately 5% of people older than 60 years develop an abdominal aortic aneurysm, and the male-female ratio is 3:1. Other risk factors include smoking, hypertension, and a family history of an aneurysm. Abdominal aortic aneurysms are caused atherosclerosis in 90% of patients; 5% of aneurysms are inflammatory.

I. Clinical evaluation
A. Abdominal aortic aneurysms are usually asymptomatic. Aneurysm expansion or rupture may cause severe back, flank, or abdominal pain and shock. Distal embolization, thrombosis, and duodenal or ureteral compression can produce symptoms.
B. Physical examination. Almost all AAAs greater than 5 cm are palpable as a pulsatile mass at or above the umbilicus. Abdominal aortic aneurysms range from 3 to 15 cm in diameter.

II. Laboratory evaluation.
Complete blood count, electrolytes and creatinine, blood urea nitrogen, coagulation studies, blood type and cross-matching, and urinalysis should be obtained.

III. Radiologic evaluation
A. Abdominal cross-table lateral films allow for estimation of aneurysm diameter.
B. Ultrasonography and computed tomographic (CT) scanning demonstrate AAAs with an accuracy of 95% and 100%, respectively.

IV. Elective management of abdominal aortic aneurysms
A. Small aneurysms can be followed using ultrasound or CT scan every 6 months.
B. Indications for repair include symptomatic aneurysms of any size, aneurysms exceeding 5.0 cm, those increasing in diameter by more than 0.5 cm per year, and saccular aneurysms.
C. Preoperative management includes optimizing cardiopulmonary function and placement of a pulmonary artery catheter or a central venous line. An arterial line permits continuous BP and blood gas monitoring. Two peripheral venous catheters should be placed.
D. Operative management. The aneurysm is approached through a midline abdominal incision and exposed by incising the retroperitoneum.
E. The duodenum and left renal vein are dissected off the aorta. After heparinization, the aorta is cross-clamped first distal and then proximal to the aneurysm. Aortotomy is then made and extended longitudinally to the aneurysm "neck," where the aorta is either transected or cut in a T fashion. The aneurysm is opened, thrombus is removed, and bleeding lumbar arteries are suture ligated. Using a tube or bifurcation graft, the proximal anastomosis is performed to nonaneurysmal aorta. The distal anastomosis is completed at the aortic bifurcation (tube graft) or at the iliac or femoral arteries (bifurcation graft).
F. Endovascular treatment of AAA uses a catheter to place a stent-graft. Early results suggest an 83% success rate and less than 6% mortality.
Orthopedic Fractures and Dislocations

Harry Skinner, MD
Michelle Schultz, MD

I. Clinical evaluation of the injured limb

B. Clinical features of fractures
1. Pain and tenderness. All fractures cause pain in the neurologically intact limb.
3. Deformity. Change in length, angulation, rotation and displacement.
4. Attitude. The position of the fractured limb is sometimes diagnostic. The patient with a fractured clavicle usually supports the limb and rotates his head to the affected side.
5. Abnormal mobility and crepitus: These signs should not be sought deliberately because pain and injury may result.

C. Clinical features of dislocations
1. A dislocation occurs when the articular surfaces of a joint are no longer in contact. Subluxation (partial dislocation) is a less severe condition that occurs when the orientation of the surfaces is altered but they remain in contact.
2. Pain and tenderness. Severe pain may be completely relieved when the joint is relocated.
3. Loss of motion. Both active and passive motion are limited in dislocations.
4. Loss of normal joint contour. In the anteriorly dislocated shoulder, the deltoid is flattened and the greater tuberosity of the humerus is no longer lateral to the acromion.
5. Attitude. The patient carefully holds the anteriorly dislocated shoulder in abduction and external rotation.
6. Neurologic injury. The incidence of neurologic injuries is much higher with dislocations than with fractures. Shoulder dislocations are often associated with axillary nerve injury. Posterior dislocations of the hip can result in sciatic nerve contusion. Careful examination for neurologic status is indicated before any intervention.

II. Clinical description of fractures
A. Anatomic location
1. What bone is fractured?
2. Where on the bone is the fracture?
   a. Metaphyseal - at the flare of the bone.
   b. Diaphyseal - fracture through the diaphysis (proximal, middle, or distal third of shaft).
   c. Epiphyseal - fracture at the end of the bone.
3. Salter classification of fractures (children):
   a. Type I. Fracture through physis, between the epiphysis and metaphysis.
106 Orthopedic Fractures and Dislocations

b. Type II. Fracture through physis, involving the metaphysis.
c. Type III. Fracture through physis, involving the epiphysis.
d. Type IV. Fracture through physis, involving the metaphysis and epiphysis.
e. Type V. Crush injury to physis, between the epiphysis and metaphysis.

B. Bony deformity: Describe any change in bone length, angulation, rotation, or displacement.

C. Direction of the fracture line. Describe the radiographic direction of the fracture.
1. Transverse - perpendicular to the long axis of the bone
2. Oblique - fracture is at an angle to the bone.

D. Comminution: Fracture with more than two fragments.

E. Open vs. Closed: In an open fracture the bone protrudes through the skin.

F. Greenstick Fracture: One cortex is broken while the other remains intact

III. Radiological evaluation of fractures. A minimum of two views at right angles to each other should be obtained. Visualize the joint above and below the injury and check for soft tissue swelling. Views of the uninjured extremity are often useful for comparison in children.

IV. Management of fractures

A. Fracture reduction
1. The fracture must be restored to a normal anatomical position
2. Muscle spasm should be relieved with traction, analgesics, and muscle relaxants.
3. Bones must be in apposition, properly aligned in linear and rotatory directions, and set to proper length.
4. Fractures should be held in place with a splint or cast.

B. Indications for operative treatment
1. Failure of closed methods to reduce or maintain reduction of the fracture.
2. Displaced intraarticular fractures, where the fragments are sufficiently large to allow internal fixation.
3. Multiple injuries - in a multiple trauma patient, operative treatment can allow early mobilization. Early mobilization can sometimes avoid the morbidity and mortality associated with prolonged recumbency.

C. Upper extremity fractures and dislocations
1. Distal radius fracture is often associated with fracture of the ulnar styloid. Treatment consists of closed reduction, casting and elevation of the extremity until swelling subsides. After reduction, check alignment with an x-ray, and rule out median nerve injury.
2. Forearm shaft fracture: In adults, radius and ulna shaft fractures require open reduction and internal fixation.
3. Humerus fracture: X-ray the entire bone and check for radial nerve injury (wrist drop). Humerus fractures are usually treated with a collar and cuff sling or coaptation splint.
4. Clavicle fractures. Subclavian artery and brachial plexus injury may occur. The fracture should be splinted with a figure of eight bandage or sling. Clavicle fracture rarely requires surgery.
5. Anterior shoulder dislocation occurs when the humeral head has been forced anterior to the glenoid. It is usually caused by extension force applied to abducted arm. The patient presents with the arm in
slight abduction, and he cannot bring his elbow to the side. There is a slightly depressed deltoid prominence and arm motion causes pain. Axillary nerve injury may occur, causing a sensory deficit over the deltoid. Treatment consists of reduction with gentle traction.

6. **Posterior shoulder dislocation** occurs when the humeral head has been forced posterior to the glenoid. Dislocation may occur secondary to seizures or electrocution. The arm is held in adduction with internal rotation. Treatment consists of reduction with gentle traction.

D. **Lower extremity fractures and dislocations**

1. **Femoral neck fractures:** Osteoporotic bone predisposes to this intracapsular fracture. Internal fixation or endoprosthesis (artificial hip) are required.
2. **Intertrochanteric fractures** usually occur in the elderly after a fall. The fracture is located outside the joint capsule. Treatment consists of internal fixation.
3. **Femoral shaft fracture:** Early intramedullary nailing is recommended in adults. This fracture is rarely associated with a fat embolism syndrome.
4. **Patella fracture:** If the bone is nondisplaced, it can be treated in a cast. If it is displaced more than 2 mm, it should be treated with internal fixation. Quadriceps function should be checked.
5. **Tibial shaft fracture** can be treated closed or with internal fixation.
6. **Ankle fracture:** Evaluate the stability of the ankle fracture by examining the joint space between the talus and tibial plafond. Unstable injuries require internal fixation.

E. **Knee injuries**

1. **Knee ligament testing**
   a. **Varus/valgus femur stress test.** The examiner stabilizes the femur, and pressure is exerted outward or inward at the ankle; a tear of the collateral ligament is indicated by excess mobility.
   b. **Anterior drawer test.** Pull tibia anteriorly with the knee flexed 90 degrees to test for tear of anterior cruciate ligament.
   c. **Posterior drawer test.** Push tibia posteriorly with the knee flexed 90 degrees to test for tear of the posterior cruciate ligament.
2. The most common ligamentous injuries are tearing of the medial collateral ligament by a blow from the lateral side of the knee, and tear of the anterior cruciate ligament by twisting on a planted foot. Brace immobilization is usually sufficient for medial collateral ligament tears.
3. Dislocation of the knee often results in multiple ligament injury. Popliteal artery trauma should be excluded. Immobilization of the knee, followed by ligament reconstruction should be completed.
Ankle Sprains

A sprain is the most common ankle injury. Injury may range from minor ligamentous damage to complete tear or avulsion. Sprain occurs when stress is applied while the ankle is in an unstable position, causing the ligaments to overstretched. Stresses usually occur during running or walking over uneven surfaces.

I. Clinical evaluation
A. Ligaments of the lateral ankle consist of the anterior talofibular ligament, calcaneofibular ligament, and posterior talofibular ligament.
B. Sprains may be classified as first-degree, involving stretching of ligamentous fibers, second-degree, involving a tear of some portion of the ligament with associated pain and swelling, and third-degree, implying complete ligamentous separation.
C. An inversion injury is the most common type of sprain, causing damage to the lateral ligaments.

II. Physical examination
A. The examiner’s fingertips should be used to check the anterior capsule and medial and lateral ligaments.
B. Anterior draw sign suggests significant injury. The sign is elicited by grasping the distal tibia in one hand and the calcaneus and heel in the other and sliding the entire foot forward. This is done both with the ankle in neutral position and with 30° of plantar flexion. With disruption of the anterior or lateral ligaments, 4 mm or more of anterior shift will occur.
C. Passive inversion of the ankle may produce pain. Swelling occurs anterior to the lateral malleolus at the onset; ecchymoses are common.

III. Radiographic evaluation
A. X-rays are useful in cases of moderate to severe injury, helping to identify any associated skeletal injury in addition to assessing degree of ligamentous damage.
B. Stress view is obtained (with local anesthesia, if necessary) to check for talar tilt. A tilt of more than 15° is suggestive of lateral ligament injury; more than 25° of tilt is diagnostic.

IV. Management of ankle sprains
A. Grade I sprains are defined as stretch of the ligaments without disruption. Grade I sprains should be treated with rest, ice, compression with an elastic bandage, elevation, and weight bearing as tolerated.
B. Grade II sprains consist of partial tears of the ankle ligaments. Grade II sprains should be treated with rest, ice, compression with an elastic bandage, and elevation. A splint can be applied for a few days, followed by early range of motion.
C. Grade III sprains consist of a complete tear of the ligaments. Treatment of grade III strains consists of rest, ice, compression with an elastic bandage, and elevation. A splint or cast can be applied for a short period of time, followed by early range of motion.
